COMMUNICATIONS.

MEDICAL SYMBOLISM.

BY T. S. SOZINSKEY, M. D.,
Of Philadelphia.

FIG. 1.

It has been well said by some one that things are not always what they seem. In the interesting and extensive field of symbolic knowledge this is, of all places, most emphatically true. Here is a figure (No. 2). Ask an uninitiated person to

FIG. 2.

look at it and state what he sees, and his reply will likely be, "A snake partly coiled, resting on a pedestal." That is, indeed, simply what it is; but to the initiated it is representative of another and far different thing. Before such a figure, many a human being, diseased and suffering, has prostrated himself and offered up supplications for relief; to generations of the people of the Eternal City, and

regions far from, as well as near to, the famous Tiber, it appeared a god, the great god of "the divine art." It is a symbol of medicine.

In my incursions into the field of symbolic knowledge, I have made notes, among which are some pertaining to medicine. But little appearing to be generally known about medical symbolism, it has occurred to the Editor of the REPORTER, as well as myself, that an article on the subject would be read with pleasure and profit by many. I do not propose to treat the matter, however, either systematically or exhaustively; such treatment of it would require much space; but I will endeavor, in a somewhat desultory way, to go into it sufficiently to instruct a little, as well as show that it is an interesting study.

Now, to begin with, I deem it proper to define a few terms, the meaning of which should be understood, or confusion of ideas will likely be experienced. In giving the article the title of "Medical Symbolism," I have intended the word symbolism to be taken in its widest sense; I desire it to be taken as of much the same signification as emblem is popularly; that is, a figure having a different meaning besides the visible one—a meaning which to be perceived calls for exercise of the imagination. Mackenzie* and other authorities, however, hold the word emblem to be properly applicable only to a figure of two or more parts. In a device there is a motto which the picture portrays more or less clearly. Allegory is almost synonymous with emblem, in its restricted sense, and is used only in reference to a composite figure, the chief consideration in which is the beauty of form. In an allegorical figure, or composition,

* Royal Masonic Cyclopædia.

the elements of it are attributes, some of which are essential and some conventional. Essential attributes alone are, strictly speaking, symbols. Thus in a representation of the Goddess of Liberty, the cap is not a symbol, it is a conventional attribute. If a poppy be taken to represent sleep, it is a symbol. In Fairholt's work* and others, the serpent in medicine is said not to be a symbol; but this is not true, if it be taken to represent the god of medicine, which was done, as I have intimated above, by the Romans. Evidently, if the word symbol were taken as of this narrow meaning, there are very few general medical symbols. In taking it, as I do in this article, to be of much the same meaning as emblem, a word applicable to any mystic figure or any kind of attribute, I do no more than Fairholt says it would be wise to always do. Any figure, then, having another besides its ordinary signification, may be regarded as a symbol.

I have said that the god of medicine was represented and worshipped by the Romans in the form of a snake or serpent; this curious creature was regarded by them as being, to all intents and purposes, *Æsculapius* himself. As is very generally known, medicine did not receive a great deal of attention, by that extraordinary people, until a comparatively late date. It was in the year 293 before the Christian era that a move was made to introduce the worship of the god of medicine. This was ordered by the Sibylline Books, in order to cut short a great pestilence. How this was done we are graphically told by Ovid.† It is a remarkable story and must be known, if one would understand, according to some, the reason why the god was given the serpentine form, the serpent being generally regarded as only an attribute of him at his chief residence, the great *Æsclepiion* or Temple of Health at Epidaurus, his birthplace. A commission on sailing around to the Grecian city, to bring home with them the god, were led for some reason or other to believe that a snake, or rather viper, which entered the ship, was the divine personage they were sent for. On returning with this precious being on board, it, or rather he, took up his abode on an island‡ in the Tiber, where he was subse-

quently worshiped, a great temple being erected for him.

What species of serpent it was which played the important part just indicated, is an interesting matter. In Pliny's work it is said: "The *Æsculapian* snake was first brought to Rome from Epidaurus, but at the present day it is very commonly reared in our houses even, so much so, indeed, that if the breed were not kept down, by the frequent conflagrations, it would be impossible to make head against the rapid increase of them." From this statement one may justly infer that it was not a decidedly venomous snake. A species of viper still common in Italy is believed to be the identical reptile. It reaches a length of about two feet. It has been described under the name of Columbar *Æsculapii*. It is spoken of under this name in Cuvier's great work.* That learned naturalist says that it is more bulky and not so long as the col. elaphsas, or four-striped adder, and continues, "It is brown above; strawy yellow beneath and on the sides; and the scales of the back are nearly smooth." After the brief description he adds, "It is that which the ancients have represented in their statues of *Æsculapius*; and it is probable that the serpent of Epidaurus was of this species. N. B.—The col. *æsculapii* of Linnæus is a totally different species, and belongs to America." The columbar *æsculapii*, Sh. is closely related, if not identical with the viper communis, or pelias berus, of which Figuier says,† "It is not improbable that it is the *echis* of Aristotle and the *vipera* of Virgil, as it is the *manaso* of the Italians, the *adder* of the country people of England and Scotland, and the *vipère* of France."

It, of course, follows from what has just been said that the adder spoken of is the serpent which should always be shown in medical symbolism.

I would ask the reader to turn with me now to the shore of the Saronic bay, to the Peloponnesian city Epidaurus, a place dearer than Salerno, or even Cos, to every lover of the annals, historical and legendary, of the healing art. There is but little about it at present to indicate its ancient glory.‡ But for the ruins in the vicinity and the imperishable records we have of them, one would

names indicate, on islands of comparatively small size. I need hardly say that there are excellent sanitary reasons for placing hospitals in the country, and especially on insular sites.

§ Vide Leake's "Travels in the Morea."

* A Dictionary of Terms of Art.

† Metamorphoses, b. xv.

‡ In his "Historia Naturalis," Pliny states that "Temples of Health were placed by the Romans without the city, and afterwards on an island." This was customary with the Greeks, too. They did not relish much more than the Romans having such institutions in their midst. The Epidaurian Oracle was without the town, and other notable ones, such as Rhodes, Cnidus and Cos, were, as the

not care to linger long about the scraggy village. It is chiefly the pages of Pausanias,* that observing and inquisitive old Grecian traveller, which tell the physician most of what is interesting to him about the place. On the plain five miles or so west of the town, was the great seat of worship of Æsculapius, the primary and perhaps greatest temple of the god of medicine, to which crowds came for ages from all parts of Greece. The Epidaurian oracle is gone; it is silent as the vanished millions who sought the means of health and life from it; but an impress of it is still felt, and will last forevermore. To this long-renowned sanatory retreat one must turn who wishes to become acquainted with the most important of medical symbols.

The statue of Æsculapius, at Epidaurus, was a remarkable piece of work, by Thrasymedes. Time has put it, with many another treasure, out of sight. It consisted of ivory and gold. When Pausanias visited the place, which was in the second century of our era, he drew from the inhabitants an interesting account of it. The figure was manly and handsome, Zeus-like. It was seated on a throne. One hand rested on the head of a serpent, and in the other was a staff. By the side of the god, lay a dog. In this, one has a very expressive allegorical representation of the healing art.

The statues of Æsculapius were, for the most part, ideal, and as might consequently be expected, varied greatly in their details; but there was a serpent connected with each of them, in one way or another. In some the great healer is represented as a bearded old man. The beard was occasionally absent, which I think was wise; for the conscientious physician should have nothing about him, which he can dispense with, which would serve to spread disease. It is said that Dionysius, king of Sicily, on conquering the Morea, ordered the golden beard to be taken off the Epidaurian god, for the peculiar reason that "it was unbecoming and unjust for the son to have a beard when the father [Apollo] had none." In the famous colossal head now and since 1866 in the British Museum, which seems to be that of a splendidly developed man in his prime (what it should be as that of the image of an ideal physician), the beard is of but moderate length, and is waved like the somewhat long hair. This noble remnant of Greek art, one of the finest in the museum, which is saying a great deal, Nichols † regards "as scarcely less remarkable"

than the celebrated "Venus of Milo" in the Louvre, both of which were found, the former in 1828, in the island of Melos, and came originally, it is surmised, from Cnidus, the seat of an æsclepiion, with those of Rhodes and Cos, of great renown in the fifth century before the Christian era.

In the left hand of some figures of the god there is a scroll—a very appropriate symbol—and in connection with not a few representations of him, a little child, or dwarf, wrapped in a mantle, stood by his side. Occasionally a cock, or crow, or goat, was given.

As I have said, a serpent was always shown in the representations of Æsculapius. It is, in some cases, coiled around a post,* by the side of which the god stands, and in some it is coiled around a staff, which he holds in his hand. The staff is sometimes given as knotty.

In this connection I may speak specially about the staff and snake, as it is usually designated, of the god, about which there seems to be considerable misconception and confusion prevailing. As I have stated, the serpent is only sometimes represented as coiled around the staff, an attribute, indeed, which is not always present. Now, when the staff is given bearing a serpent, it must not be regarded as a magic wand, for Æsculapius had nothing of the kind. A very different personage, Mercury, had a wand, or rather caduceus, which, strange to say, is taken by many to be a symbol of medicine. That is, Mercury's caduceus, which is not of medical import at all, is accorded to Æsculapius, who really had none. I repeat, there is no such a thing as an Æsculapian wand, if

wand be taken as meaning a rod or staff possessed of mysterious power. A staff with a serpent twined around it, however, is an expressive medical symbol. It may properly be regarded as an emblem of Æsculapius. I give a good example in Fig. 3, copied from a plate in De Wilde's rare old work.† The serpent may be taken as a symbol of the god, and the staff as one to indicate the perambulatory character of the physician's calling. Regarding the knots as expressive of difficulties in the art and practice

FIG. 3. of medicine is very fanciful, but not infrequently done.

I deem it not amiss to give a cut (Fig. 4), of the caduceus of Mercury, in the hope of better removing misapprehension in regard to it. It is

* Itinerary of Greece (Ællados Periegesis).

† Handybook of the British Museum, 1870. An excellent engraving of the head appears as the frontispiece.

* This, or even the staff, may be a remnant of tree-worship. Vide infra.

† Gemmæ Selectæ. Amsterdam, 1703.

given as shown, but not very correctly, on a seal used by the United States Marine Hospital Service.

FIG. 4.

It is an appropriate trade symbol, Mercury being the god of commerce as well as the messenger of the gods; but it is more especially a symbol of peace, the god being the great peace-maker. Traditional history relates that in his rambles one day, he saw two snakes fighting, and laying his

wand, which was originally an olive branch, between them, was delighted to discover that it had the power of putting an end to the encounter. Hence the presence on the wand of the two serpents, which, of course, it would be wise to represent as belligerent. Mercury being an adept thief, was regarded as the god of rogues; from which fact taking his caduceus as a symbol of medicine is a left-hand sort of compliment to the physician, even if he is one who regards his profession chiefly as a trade. And this brings to mind a very truthful remark of Bacon*, namely, "If physic be a trade, it is the trade of all others the most exactly cut out for a rogue." Another function of Mercury, which I may mention, was to attend to dying persons, to unloose their souls and drive "them down the Stygian waves," as we are told by Virgil.† It is hardly a part of the physician's proper function, I submit, to do that.

How to account for the association of the serpent with the god of medicine is a trifle puzzling to many.‡ Saying that it is symbolic of prudence and renovation is not quite satisfactory, although it may be properly taken as of such import. "As wise as a serpent," is an everyday saying. Casting of the skin is said to be the basis of the idea of renovation or rejuvenescence. Taking it as expressive of the idea of convalescence is not out of the way, for it undergoes, every spring, a remarkable change from a state of lethargy to one of active life, under the strengthening rays of Apollo himself, as will be seen later, the original Grecian god of medicine. This notion is well portrayed in Mrs. Palliser's interesting work,|| in the device of the Rinovati Academy.

The commonness of a tame, but somewhat ven-

omous serpent, the adder already spoken of, about and in the Epidaurian Temple of Æsculapius, has been advanced as explaining the association of the reptile with medicine. This may have had something to do with it.

After referring to some strange curative virtues, attributed to vipers, Pliny* says: "Hence it is that the snake is consecrated to Æsculapius." Here is one of the examples given by the rather credulous old Roman: "It is a well-known fact that all injuries inflicted by serpents and those even of an otherwise incurable nature, it is an excellent remedy to apply the entrails of the serpent itself to the wound." The principle is evidently the same as that illustrated in applying a hair of the dog to cure the wound caused by the animal.

Still another reason for the association has sprung from the reputed power of the serpent to discover herbs of curative virtues. This is largely based on a traditional episode in the history of Æsculapius, which reminds one of the German story of the Snake Leaves, told by Grimm.† It seems that on one occasion while thinking what treatment to resort to in the case of one of his patients, Glancus, a serpent appearing and twining itself around his staff, he killed it, whereupon another came, bearing in its mouth an herb with which it restored the dead one to life. The god used the same herb with similar effect on the human subject. The miraculous feature of this explanation puts it on a par with such as one would expect from the Indians, whose "medicine man," too, is apt to have a snake at hand, as he is also, I may say, to make himself bird-headed,‡ reminding one of the Egyptian Thoth, and others.

I am of the belief, however, that the remarkable association of the serpent with the god of healing must be largely explained in yet another way. There is good reason to hold that we have in it a remnant of serpent-worship, a wonderfully wide-spread cultus, still kept up by the Nagas (literally snakes) of India,|| and others. Epidaurus was open to frequent communication with Egypt, where the serpent played a great religious role, being in different forms representative of good and evil. Says Sharpe in his excellent little

* Advancement of Learning.

† Æneid, b. iv.

‡ It is worth while to remark that, in his life of Cleomenes, Plutarch states that it was believed that after death evaporation of "the marrow" produces serpents, and that "the ancients knowing this doctrine, appropriated the serpent, rather than any other animal, to heroes."

|| Historic Devices, Badges and War-cries.

* Op. cit.

† Household Tales.

‡ Vide engraving in "False Gods" by F. S. Dobbins.

|| Says Dr. Birdwood, in his "Indian Arts": "The worship of the snake still survives everywhere in India, and at Nagpur was until very recently a public danger, from the manner in which the city was allowed to be overrun with cobras."

work,* "The venomous snakes and those that were not venomous were alike honored, the first as the gods of evil, and the second, as gods or rather goddesses of good." The serpent of good is always represented as prevailing. The creator of the world was given a serpentine form. The sect of Gnostics, called Ophites, taking the world to be evil, attributed its creation to the serpent of evil, Eve's acquaintance. Evil in the shape of disease might be expected to be overcome by the serpent of good.

(To be continued.)

A RARE FORM OF RETINAL AFFECTION.

BY M. LANDESBURG, M. D.,
Of Philadelphia.

Mooren† first drew the attention of the medical profession to a peculiar form of retinal affection, which he saw but in one instance during the long term of his ophthalmic practice, and of which no mention had been made before in the oculistic literature. This affection, which he calls "retinitis punctata albescens," was characterized by innumerable punctate, whitish spots, resembling crystals of cholesterine, which were spread over the whole retina. The communication of Mooren's unique case was very soon followed by the report of one similar case, made by Kuhnt, and of three others by Hirschberg, to which has lately been added one case by Swan M. Burnett. As a further contribution to the knowledge of this rare and highly interesting form of retinal affection, I beg leave to present the following three cases:

Case 1. Bookkeeper H., 53 years old, applied to me, August 26, 1877, on account of a dark spot in the centre of the visual field of his right eye, which has gradually developed during the last six weeks, greatly impairing vision. Examination showed:

Right Eye.— $M = \frac{1}{40}$. $V = \frac{15}{40}$. With the naked eye Jaeger 9, with convex 10 Jaeger 4. The visual field, measured at one foot distance from the perimeter, is of normal extent in its outlines, but shows in its centre a ring-shaped scotoma of sixteen lines in diameter. The color-perception within this scotoma is entirely abolished for red and green, and slightly impaired for blue. White is perceived as dirtyish-gray. Pupil and tension are normal. The optic disc is of pinkish color, with well-defined border and normally arranged

vessels. The region between the optic disc and macula lutea is thickly studded with numerous, minute, yellowish-white points and dots, which appear in groups and isolated, leaving free the track of the vessels. On the inner border of the macula lutea there is a small, irregularly-shaped, whitish-glistening spot, and close to the latter a flat extravasation of blood. A somewhat larger extravasation of blood is situated below the inner border of the optic disc. The retinal tissue of this area is slightly veiled by a delicate diffuse opacity, and presents a dull-reddish hue. The faint exudation shades off into the adjacent retina, which altogether with the whole remaining surface shows absolutely normal condition. Only one inferior branch of the ophthalmic vein is slightly tortuous and hyperæmic. All blood-vessels can be followed up to their finest ramifications.

Left Eye.—Amaurosis. Refracting media transparent. Optic disc atrophic; blood-vessels very thin and totally obliterated towards the macula lutea. The region between the latter and the optic disc is occupied by numerous, minute, darkish-brown spots and dots, which slightly raise from a striated and dirty-brownish surface, through which the choroidal vessels can be faintly seen. The retinal elements are totally destroyed in this area, the irregular outlines of which are bordered with a darkish rim. There are no other anomalies on the retina.

General health has always been good. There is no history of syphilis or malaria. Liquors are not used at all; tobacco but moderately. Urine is normal, of acid reaction and of specific gravity of 1018.

The only assignable cause of the loss of his eyesight patient can give is the poor, inadequate light, under which he has been obliged to do heavy work through long years. The right eye, which has been blind for two years, has begun suffering under similar symptoms, to those under which its fellow is now laboring.

My treatment consisted in the use of mild derivatives and syrupus Giberti in moderate doses, in connection with periodical applications of fleurel-loups. The improvement of the morbid process progressed slowly but steadily. The first change for the better was noticed in the condition of the scotoma, which gradually became brighter, smaller and more transparent, and finally contracted to a fine, pellucid spot, which remained in the centre of the visual field long after the color-perception had been restored to its normal condition, and vision had increased to $\frac{1}{2}$. The improvement in the functional disturbances was, however, not

* Egyptian Mythology.

† See "Five Lustra of Ophthalmic Practice." Wiesbaden, Bergman, 1882.

attended with any material change in the morbid process proper of the retina. The latter remained in full height until the fifth week of treatment, when vision had reached $\frac{1}{2}\%$ and scotoma had considerably diminished. Then only reparation commenced, starting with the absorption of the retinal exudation, which now proceeded very rapidly. The retrogressive course of the yellowish-white points and dots began at the seventh week of treatment, after vision had reached $\frac{1}{2}\%$ and scotoma had entirely vanished. The points and dots faded but gradually, disappearing from the view only at the end of the twelfth week of treatment. The extravasations of blood remained longest, and winter passed off before absorption had completed its course. A few pigment deposits were the only traces of the affection left on the retina.

Case 2. Butcher G., 39 years old, applied to me February 7, 1880, on account of central obscuration in the visual field of his right eye, which has developed during the last few days. Examination showed:

Right Eye.— $V=\frac{2}{3}\%$. Jaeger 7. Visual field normal in its outlines, but showing central scotoma of elliptiform shape, the axes of which, measured at one foot distance from the perimeter, are respectively 15 and 9 lines in length. Within this scotoma the color-perception is totally lost. White appears gray. Refracting media are transparent. Optic disc, peri-papillary border and vessels are normal. Inside from the optic disc, at a distance from the latter of two papillæ in diameter, there are numerous ecchymoses, clustered close to each other in radiating streaks, which form a crescentic figure, with the opening towards the macula lutea. The retinal tissue between the ecchymoses and macula lutea is slightly infiltrated and swollen, and covered with numerous minute fatty-glistening spots, which are either isolated or in groups. There are no morbid changes in the macula lutea itself, but the latter is dark red, and shows in its lower border a fine hemorrhagic effusion. The whole remaining surface of the retina is covered by a very delicate, diffuse opacity, and sprinkled over with numerous white, opalescent dots, which, however, keep aloof from the course of the retinal blood-vessels. The latter are normal. Only one venous branch, which, emerging from the optic disc, runs downwards, and turns abruptly to the macula lutea, is slightly hyperæmic and tortuous.

Left eye is normal.

Patient is a perfectly healthy man, of robust constitution. There is no history of syphilis, or of

intemperance either in liquors or tobacco. Urine is normal, of acid reaction, and of specific gravity of 1019. No assignable cause of the affection can be given.

The result of the treatment with subcutaneous injections of muriate of pilocarpine (half a grain *pro dosi*) was as follows:

After the Twelfth Injection.— $V=\frac{3}{3}\%$. Scotoma separated into two lateral halves, leaving entirely free the fixation-point.

After the Twentieth Injection.— $V=\frac{2}{3}\%$. Instead of the scotoma there are only two delicate lateral shadows, which do not impair vision. They entirely vanish after a short time. The white dots on the retina have faded but very little. The color of the macula lutea is slightly reddish, and the hemorrhagic effusion in course of absorption. The region between the macula lutea and the optic disc has regained its transparency, and the white deposits have disappeared in some parts, while they have only become fainter and sparser in others. The crescentic figure, formed by the striated extravasations of blood near the optic disc, has broken into small reddish spots and points, raising from a reddish-gray base.

With this condition of his eye patient is discharged from treatment April 20th. The favorable result remains stationary. The pathological changes in the background of the eye subside but slowly, leaving finally no other alterations on the retinal tissue but a few pigment-spots.

Case 3. Merchant L., 51 years old, applied to me, December 19, 1882, with the complaint that a cloud has developed during the last few weeks before his left eye, which greatly interferes with the central fixation of objects. The vision of his right eye has also failed, although morbid symptoms proper have not yet come into notice. Examination shows:

External appearance of either eye normal. Vision of the left eye $\frac{1}{3}\%$, of the right eye $\frac{1}{2}\%$. The right eye reads with the help of convex 10 Jaeger 1, the left eye only Jaeger 4. The outlines of the visual field in either eye are limited upwards and inwards, to a greater extent in the left eye. The latter, shows besides a central scotoma of oval shape, the axes of which, measured at one foot distance from the perimeter, are 13 respectively 8 lines in length. Within this scotoma the color-perception is lost for red and green, and slightly impaired for blue. The right eye presents a small area around the fixation point, within which the principal colors appear somewhat fainter than in the other parts of the visual field. Refracting media are normal in either eye.

Left Eye.—Optic disc and blood-vessels normal. Peri-papillary region distinct. The inner border of the optic disc is surrounded, wall-like, by numerous, striated, linear extravasations of blood, closely aggregated to each other. The whole region between the striated extravasations and the macula lutea is occupied by numerous, minute, whitish-yellow points, which raise, either isolated or in groups, from a gray-reddish and slightly infiltrated surface. Inside from the macula lutea, almost touching its border, there is a corona of punctiform ecchymoses, with a whitish speck in its centre. The fovea centralis itself contains a small pinkish spot. In the vicinity of the morbid deposits the veins mostly are dark-red and tortuous, the arteries thin. Some vessels, which run directly from the optic disc to the affected parts of the retina, are veiled by the retinal infiltration. The remaining surface of the retina with its vessels presents no anomaly whatever.

Right Eye.—Optic disc and vessels normal. Peri-papillary region distinct. Two minute, linear extravasations of blood are situated upwards and inwards from the papillary border, and several larger ones near the macula lutea, the color of which is dark-red. On the space between the macula lutea and the optic disc there are scattered about ten to twelve whitish dots; two somewhat larger, yellowish and fatty glistening spots are situated near the macula lutea. The retinal tissue in this region is slightly infiltrated, and the veins are hyperæmic. The remaining surface of the retina is absolutely normal.

Patient is a healthy man of robust constitution, whose organs are in perfect order. Urine is normal, of acid reaction, and of specific gravity of 1019. He is in all other respects temperate but in the use of tobacco, in which he has immoderately indulged for many years past. He smokes daily from about fifteen to twenty very strong and large cigars. No other cause of the affection could be elicited. Starting from the supposition that the abuse of tobacco might stand in direct connection with the affection, I tried to prevail upon the patient to refrain from his bad habit, but to no purpose. His passion was stronger than his will. The conclusion would certainly be too rash that the abuse of tobacco had had nothing to do with the affection; but on the other hand, we cannot shut our eyes to the fact that treatment had the effect to cure the trouble, notwithstanding the injurious influence continued to act in full force.

The application of fleur-le-loups, to which I first resorted, had the following result:

AFTER THE FIRST APPLICATION.

December 26.—Vision of the left eye $\frac{1}{20}$. The cloudiness before the eye much brighter. Central scotoma smaller and more pellucid.

Vision of the right eye $\frac{1}{20}$.

AFTER THE SECOND APPLICATION.

January 5, 1883.—Vision of the left eye $\frac{1}{4}$. Cloudiness almost subsided. The central scotoma is replaced by a fine shadow, within which there is a dullness for the finer shades of colors, whereas the principal colors are correctly distinguished. Vision of the right eye $\frac{1}{20}$. Perception of colors and fixation-point normal.

January 13.—Vision $\frac{1}{2}$ with either eye. Binocular vision $\frac{1}{20}$. Field of vision normal in either eye. The central shadow in the left eye is brighter and more pellucid.

The morbid alterations in the retina are in the course of resorption in the right eye, but unchanged in the left one.

AFTER THE THIRD APPLICATION.

January 18.—Vision of the right eye $\frac{1}{2}$. Ecchymoses fainter, thinner, and partly resorbed; the whitish-yellow dots have considerably faded.

Vision of the left eye $\frac{1}{20}$. Pathological deposits in the retina unchanged. Two fresh, small extravasations of blood near the macula lutea. The central shadow more opaque. The principal colors appear fainter and dimmer. Field of vision normal.

The diaphoretic treatment to which I now resorted, in combination with small doses of bichloride of mercury, had the most favorable result.

March 22, examination showed:

Vision of the right eye $\frac{1}{20}$. The white dots totally resorbed; only a few traces of the extravasations of blood. The affected part of the retina restored to normal condition.

Vision of the left eye $\frac{1}{20}$. Scotoma vanished. Color-perception normal. Pathological changes in the retina in full progress of resorption. The whitish dots less numerous and but thinly scattered in the vicinity of the macula lutea. The latter presents normal appearance. The radiated ecchymoses partly resorbed; the larger extravasations of blood flatter and brighter. The veins less tortuous, the arteries more filled up.

In this condition of his eyes patient reassumes in full the duties of his business, and withdraws from any further control.

2006 Arch street, Philadelphia.

—Mr. Lister has been offered and has accepted a baronetcy.

A NEW BATTERY SOLUTION.

BY CARL SEILER, M. D.,

Lecturer on Diseases of the Throat and Nose and Instructor in Laryngology at the University of Pennsylvania.

Every one who has had much to do with batteries for medical purposes and for the galvanocautery, in which bichromate of potash solution is used in connection with sulphuric acid as the exciting fluid, has been annoyed by the formation of ruby-colored crystals. These crystals, which are very hard and insoluble in cold water, cover the surface of the zinc plates, and are formed in the interstices of the carbons, besides forming a thick and hard crust at the bottom and at the sides of the cup containing the fluid. They are more readily formed in cold weather than during the warm season, and can be dissolved only by boiling water. Being non-conductors of electricity, they increase the resistance of the carbons to such an extent as to materially interfere with the proper action of the battery, and thus often only a feeble current is obtained from a powerful instrument. These crystals, commonly called chromo-alum, are, in reality, a double salt of chromo-sulphate of potash, the combination being favored by the electric current and by exposure of the elements of the battery to the air.

The reader, not well versed in the chemistry of batteries, may ask, Why not leave out the bichromate of potash, and only use a solution of sulphuric acid and water? The answer to this question will explain the chemistry of the new solution. When two elements, say a carbon and zinc plate, are placed in a jar containing acidulated water, and are above the solution connected by a wire, an electric current is established, which decomposes some of the water into its constituents, hydrogen and oxygen. The former, together with the acid, enters into combination with the zinc, while the oxygen, in the form of small bubbles, adheres to the surface of the carbon, and being a non-conductor of electricity, soon stops the action. This is termed polarization. In order to prevent this, or at least reduce it to a minimum, a substance is added to the solution, which has a strong affinity for the oxygen, and thus prevents the coating of the carbon plate. There is, perhaps, no better deoxidizer known than chromic acid, and as it forms a large part of the cheap commercial salt bichromate of potash, this is added to the sulphuric acid and water to form the battery solution. It is, therefore, the chromic acid which acts, being set free from its combination with the potash by the action of the sulphuric acid, and we thus have a solution of sulphate of potash and of chromic

acid, with a surplus of sulphuric acid and water, in our existing fluid. If pure chromic acid instead of bichromate of potash is used in making the fluid, no crystals can be formed, since no potash is present; but the crystallized chromic acid is a very expensive article, costing nearly \$2 per pound at wholesale rates. A crude non-crystallized chromic acid can however readily be made, and when added to the sulphuric acid and water will give excellent results, the plates remaining free from all crystals, and the fluid retaining its full force to the very last. A fluid made according to the following formula has given me great satisfaction in my galvanocautery battery, and it can be used, diluted one-half with water, for the ordinary medical batteries:

Bichromate of potash,	2 pounds.
Hot water,	$\frac{1}{2}$ gallon.
Sulphuric acid,	$\frac{1}{2}$ gallon.

Dissolve the bichromate of potash in hot water, and when cool add to it the sulphuric acid. This should be mixed in an earthen vessel, as the sudden evolution of heat is very apt to break a glass bottle. When cold, place the mixture, which will be quite thick, in a glass funnel, the tube of which is partly closed with asbestos, and drain off all mother liquor, which is a saturated solution of sulphate of potash. Then re-dissolve the parts remaining in the funnel in $1\frac{1}{2}$ gallons of water, and add to it 2 quarts of sulphuric acid if the fluid is to be used for the galvanocautery battery; but if it is for the ordinary medical battery, 1 quart of sulphuric acid is sufficient.

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

BY WILLIAM PEPPER, M. D., LL. D.,

Provost and Professor of Clinical Medicine in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M. D.

Infantile Paralysis.

GENTLEMEN: The first patient which I shall show you to-day is this child. The mother gives us the following history: She has had two children, one of whom died of cholera infantum. This little girl is nine months old. About the middle of July (five months ago), it was seized with general paralysis, and could move neither its hands nor feet. This was preceded for a few days by feverishness and restlessness. This condition of general paralysis lasted for two days. She then began to regain power in the right arm and left leg. Motion returned to the arm sev-

eral days before it did to the leg. In the course of three or four weeks, she began to use the left hand. Further than this, there has been no improvement in the ability to move the limbs. She has had no spasm of any kind, nor has she had any injury sufficient to suggest a traumatic origin of this paralysis. She had not been exposed to wet or dampness at any time.

This is an example of infantile paralysis, but it differs from ordinary cases of this disease, in the fact that the paralysis has been so general. As you are aware, infantile paralysis commonly comes on about this period of life, that is, during the first dentition, somewhere between the ages of twelve and thirty-six months. The causes of this affection are obscure. It sometimes undoubtedly comes from direct exposure and severe chilling of the body, but in many cases, it comes on without any apparent adequate cause. It is usually preceded by just such symptoms as those described by the mother of this child. For a few days, the child will evidently be unwell, feverish, restless, indisposed to be moved, crying and fretting, with a poor appetite, and perhaps with some little gastric disturbance, as is shown by vomiting. The child is, perhaps, put to bed in this condition without any evidence of paralysis, but in the morning it will be found to be paralyzed. The disease comes on then after an uncertain period of indefinite sickness, which is evidently sympathetic with the trouble in the spinal cord.

This case illustrates very distinctly another common feature of infantile paralysis, namely, that nearly always the loss of power is greatest at the beginning of the attack. The paralysis affects a larger number of members or muscles than remain permanently paralyzed, so that after a few days the paralysis begins to clear up and those parts which have been least affected regain their power, leaving a certain number to be permanently paralyzed, or paralyzed for a longer period.

In this child, neither the bladder nor the rectum have been involved. This is the usual history. The deeper portions of the cord where the fibres going to the bladder and the rectum traverse, are not, as a rule, involved in the disease; for, as you know, the seat of the lesion in infantile paralysis is in the anterior horn of gray matter of the cord, and in the anterior column in this vicinity. The condition in the beginning is one of congestion, irritation, and swelling. We can, therefore, readily understand that in these parts where the lesion is less severe, it may pass away leaving no organic change, and thus we may have cases of infantile paralysis which recover completely in the course of two or three weeks, more commonly owing to the extreme sensitiveness of the spinal system. At this early age we find that some part of the spinal cord is so badly hurt that it undergoes degeneration and atrophies, or at least tends to do so. In such cases, the paralysis becomes permanent, and is followed by wasting of the affected muscles. Thus it is that this disease is often called atrophic infantile paralysis, because it is so frequently followed by wasting of the muscles which remain palsied; but this again depends upon the extent to which the anterolateral column and anterior horn of the cord have been injured by the original cause. This may

leave a more chronic trouble, which will pass away, leaving the integrity of the cord unimpaired; or it may be followed by wasting of the large multi-polar cells, which have a trophic influence upon the muscles, and this wasting is followed by atrophy of the corresponding group of muscles.

Let us now examine the condition of the affected muscles in this case. The child can move the right arm and hand very well. When an object is presented to her left hand, she tries to raise the arm to grasp it, but she is unable to do so, as the muscles of the shoulder and arm are paralyzed. When I put the object in her hand she clutches it firmly, showing that the flexor and extensor muscles of the hand have regained their power. This case well illustrates the way in which the disease dissects out particular muscles or groups of muscles, apparently without reference to their position. Here we find the shoulder and humeral muscles of the left side involved, and naturally, we should expect to find the muscles of the hand affected in the same way; but it is not so. There is considerable power in the right leg, and during the past few days the child has regained some power over the left limb. There has as yet hardly been time for much wasting of the muscles to take place, but I find that the muscles around the shoulder are decidedly wasted. As long as the muscles have not atrophied, you should never despair of a perfect cure. The case may keep on improving even after it has lasted for a long time. When the muscles have wasted there is great reason to fear that they cannot be restored to their natural condition.

In treating the early stage of this disease, I think that it is well to act upon the supposition that there is irritation and congestion of the spinal cord. Counter-irritation along the spine and the use of ergot, belladonna and iodide of potassium internally, are indicated. At a later stage of the disease, when as much of the paralysis as will clear away has passed off, and there remains only the permanent paralysis which is associated with a serious lesion of the spinal cord, this line of treatment does not produce good results. We then have to depend upon remedies to promote the general nutrition, as iron and cod-liver oil, with correct hygiene, taking great care that the child is dressed properly and not exposed to dampness, draughts, etc. Friction of the skin should be employed to maintain the circulation, for the child cannot take that incessant exercise by which young children maintain a healthy condition of their muscles and functions. In addition to this, there should be treatment especially directed to the paralyzed parts, hoping that the tone of the spinal centres will be sufficient to enable them to maintain their integrity and prevent disintegration and atrophy of the nerve cells, which will be followed by wasting of the corresponding muscles. I do not know that we have any remedy that specially influences the nutrition of these important nerve cells. Strychnia has no effect upon them, but acts only upon the motor nerves and the muscles. It is proper to use strychnia at a late period of the case, and it may be administered by the mouth or hypodermically, being injected into the affected muscles. The object of this treatment is to improve the nu-

trition of the muscle, and not to act upon the spinal cord. Massage, friction and passive movements should also be employed with the same object. The circulation of the skin should be stimulated by friction and warm clothing. Good results are often obtained by putting the affected member under an air pump and exhausting the air. The limb is as it were enclosed in a large cupping glass, a vacuum is created, and the blood is drawn into the part. This carefully repeated is frequently of service.

In private practice, we have scarcely the means of treating these patients as they should be treated. All that form of apparatus which has been brought to such perfection in Sweden serves an excellent purpose in the treatment of atrophic infantile paralysis.

Electricity is an important agent in the treatment of this affection, but its use requires judgment and skill. That current is employed which will give contractions of the paralyzed muscles, and the interrupted galvanic current is practically the only one which is of service. It is to be used of such a strength and with the current interrupted at such a rate, and applied over the nerve points, the nerves themselves, or the muscles, according as you get the best results. There is no fixed rule to be laid down for the use of electricity, save that the current should be moderate and used in such a way as to secure contractions of the affected muscles. As many of you know, there is a special form of reaction of the muscles to electricity, which, however, I shall not consider to-day, which indicates the approach of disintegration of the cord. It is a reversal of the normal relation of the muscles to the interrupted galvanic current, and the detection of this is, although not absolutely of unfavorable prognosis, a serious sign.

What we do for these cases in private practice is to promote nutrition by the use of iron, cod liver oil, later employ strychnia, keeping up friction of the skin, and training the parents in the use of massage and passive movements, carefully regulating all matters of hygiene, and if we have time and a suitable battery, apply the galvanic current in the way which I have suggested. These are cases which are more satisfactorily treated in institutions especially designed for this purpose, but the great objection to this treatment is its costliness, and we should have, in connection with our general hospitals, suitable apparatus for the treatment of these cases.

These cases require a long treatment, and if this is neglected the paralyzed muscles may pass into a condition of hopeless atrophy from disuse, and although the trophic centres of the cord may not be ruined by the original disease, the muscles from lack of proper treatment become hopelessly wasted.

Attention has been called to the projection of this child's stomach. Occasionally the dorsal muscles, or abdominal muscles, are paralyzed, allowing the body to fall in all directions, or great protuberance of the stomach when the child sits up. This is one of the rare cases in which there is paralytic distension of the abdomen. I have seen this condition on a number of occasions, although it has been recently described by a specialist as though it were something quite new.

Dupuytren's Contraction of the Tendons of the Hand, with Trembling.

Our next patient is a painter. He was born in Scotland, and came to this country two years ago. He comes with the statement that he has trembling of the right hand and contraction of the flexor tendons. Both his parents are living, and, as far as he knows, there is no gout or rheumatism in the family. He had two attacks of rheumatism before he came to this country, but the heart did not suffer in either attack. I refer to this point, because this contraction of the flexor tendons, which was described by Dupuytren, and is often called Dupuytren's contraction of the tendons, is one that I have commonly seen in persons of a gouty or rheumatic diathesis. It is often associated with sub-acute rheumatism. It comes on at different periods of life, but usually much later than that at which our patient presents it.

He has contraction of the tendons of the little and ring fingers of the right hand. The tendon is thickened, hardened, rigid, and evidently contracted; the fingers are more or less drawn, there is difficulty in fully expanding them, and when force is employed it excites pain. Occasionally this contraction will go on until all the tendons are involved and the hand is reduced to a state of characteristic deformity. It often happens that the affection is symmetrical. In its earliest stage, I have known it to yield to internal alterative treatment. Later, it becomes the subject for surgical treatment, but even after subcutaneous section of the tendon, it will, as a rule, be found that as long as the constitutional tendency continues, the disease will recur and the contraction again present itself.

The affection of the tendons in this patient is associated with trembling of the hand, and as he holds out his hand you see that it is the seat of a general trembling; it is not a fibrillar twitching, the whole member shaking, instead of there being a quivering of individual groups of fibres under the skin. You have probably had your attention called to those curious fibrillar twitchings which appear beneath the skin when the muscles are going to pass into a state of progressive atrophy. In that curious disease, progressive muscular atrophy, one of the earliest symptoms, occurring perhaps before the wasting of the muscle has progressed sufficiently to be recognized, is the appearance of this fibrillar quivering. This is quite distinct from the trembling which this patient presents. The left hand does not quiver as much as the right, and the tendons are not affected to the same extent.

He first noticed the trouble in the right hand about eighteen months ago. He has been engaged at painting for sixteen years. He has never had lead colic or other symptoms of lead poisoning. There is no blue line along the gums. During the past two years he has worked at painting cars, and in a great deal of his work, he cannot use a rest for the hand. Sometimes, when polishing the varnish, his hands are in cold water for one or two days at a time. During the past six months he has begun to use his left hand to some extent in striping, but he is sure that the trembling of the left hand came on before he began to employ it in this way.

The fact that this patient has been handling

lead in various ways for so long a time and has never had paralysis, neuralgia, colic, blue line on the gums, or other evidences of saturnine poisoning, led me to believe that this trembling is not dependent upon the action of lead, but is due to an affection of the sheath of the nerves, similar in character to that which has attacked the tendons. I may be wrong in this opinion, for as you know, the symptoms of lead poisoning are curiously diverse. This may be the result of the action of lead, but I am inclined to connect it with rheumatic tendency and the affection of the tendons.

It will be proper under the circumstances, to put this man on a treatment suitable for lead poisoning. If he can do it, he should give up painting; but as he probably cannot do that, he should keep his hands entirely away from lead, and when painting should, as much as he can, use a rest for the hand. He has been taking a tonic consisting of iron, quinine and strychnia; and also five grains of iodide of potassium three times a day. I would stop the tonic and increase the dose of iodide to ten grains in water on an empty stomach. With this I shall order ten drops of the juice of conium and increase the dose cautiously until we see whether or not it has a favorable effect on the muscular trembling.

Gastric Disturbance Probably Due to Incipient Cirrhosis of the Liver.

In this patient we are anxious to arrive at a correct diagnosis, and yet it is a difficult thing to do. He is a laboring man, 52 years of age. His statement is that he has always enjoyed good health, but has used liquor to excess. He states that the symptoms of the present sickness came on only six weeks ago, and expects us to believe that this appearance of extreme illness has been developed within that time. I find it difficult to do this. I think that it is more likely that he has failed to notice the disturbances which may have preceded the condition in which the symptoms have been more acute. For the past six weeks he has had frequent vomiting, has rapidly lost flesh and strength, and assumed this anæmic and cachectic appearance, and yet there has been no fever and no complaint of pain. He has not worked for twelve months, but had no trouble with digestion, and never had vomiting before six weeks ago. He vomits about once or twice a week, and usually in the morning. The matters vomited consist of "sour stuff," and sometimes in part of the food taken the previous evening, but there has never been any blood vomited. The bowels are opened without medicine about once in every three days. His best weight was 160 pounds. He thinks that he now weighs about 125 pounds. During the past six weeks he has lived chiefly on liquid food, taking about a quart of milk a day. If he takes solid food, it excites vomiting.

The rapid development of this vomiting makes it hopeful that it is not due to malignant disease. It may prove to be a case of ulcer of the stomach, but the absence of pain and tenderness, the period of the vomiting, occurring only in the morning, the character of the matters vomited, and the absence of blood, are all against the idea of ulcer. This leads us to hope that it may be one

of those cases of gastric catarrh with congestion of the liver, which may occur in a person broken down by imprudence in the use of liquor. Some of these cases very closely simulate carcinoma of the stomach, and will often give you considerable embarrassment. The fact that this is so should warn you against pronouncing an unfavorable diagnosis and prognosis. If you are unable to detect actual thickening or a distinct tumor, be careful how you are led by the severity of the symptoms, the failure of flesh and strength, and the appearance of emaciation, into the assertion that the patient has carcinoma. Of course, you are forced to consider this possibility; you may even be forced to suspect cancer; but beware how you communicate that suspicion to any other person, and you should carry out that treatment which would be of service if the disease were not malignant. If the disease is malignant, this is the line of treatment which will do the most good; whereas, if you allow yourself to hold the opinion that there is incurable organic disease of the stomach, you will lose heart, and if you tell the patient, he will of course feel that there is no use in pursuing any special line of treatment, at least with you, if you know beforehand that you are going to do him no good.

Let us now examine the stomach. The abdominal muscles are rigid, but by a little gentleness and perseverance, I am able to get my fingers down on the aorta, and if there was any distinct thickening of the walls of the stomach, I should certainly be able to detect it. The results as regards the stomach are therefore negative.

The dullness of the liver begins at the sixth rib, and does not extend below the border of the ribs. The liver is small. You have heard a great deal about the gastric symptoms of developing cirrhosis, and this is a condition which must constantly be borne in mind in diagnosing between gastric carcinoma and other causes of vomiting and wasting.

In view of the distinct history of alcoholism, the diminished area of hepatic dullness, and the absence of any demonstrable thickening or lump, I am disposed to explain this case as one of chronic gastric congestion and catarrh, connected with portal obstruction from incipient cirrhosis, rather than a case of carcinomatous disease of the walls of the stomach. Sometimes you will find grave symptoms developed, even when the condition of the liver is still entirely curable, and has not passed into an actual cirrhotic change.

I shall recommend this patient to continue the simple diet of milk and light cereals which he has employed during the past six weeks. All forms of alcohol are to be avoided. Internally I should recommend the use of bi-chloride of mercury with no other remedy, given moderately diluted on an empty stomach. I should begin with $\frac{1}{16}$ of a grain in two ounces of liquid, and gradually increase to $\frac{1}{4}$ of a grain three times a day, as it is tolerated and produces good results. In a month we shall be able to decide as to the effect of this treatment.

—Dr. Brand, of Stettin, was the first man to introduce (in 1861) the treatment of typhoid cases by cold baths.

NEW YORK HOSPITAL.

CLINIC OF PROF. WILLIAM H. DRAPER.

Reported by W. H. SEELYE, A. M., M. D.

Traumatic Peritonitis.

The patient is thirty-five years of age, a native of Ireland, married, and is employed as a stoker at the Metropolitan Gas Works, in this city. He was admitted to the hospital December 13. He gives a purely traumatic history. He was perfectly well until the night of December 12. He was then at work in the gas factory, and was struck violently in the abdomen with a heavy iron coal-shovel. Though suffering intense pain, he was taken home, and then he suffered from shock, and had a fever, followed by a profuse cold sweat during the night. He had no chill. There was great pain and tenderness in the abdomen, which continued until he was brought here, at 7 a. m., in a greatly prostrated condition. He has passed water this morning, but was not able to before. He has had no movement from the bowels since the injury was received. Has not been able to sleep because of pain and restlessness. The pain is increased on motion and by pressure. He finds greatest relief in the dorsal decubitus, and with his legs drawn up and knees flexed. On admission, his pulse was 111, respiration 28, and temperature 101.80. His urine was drawn off with a catheter, and it had a specific gravity of 1.028, contained no albumen or casts, had an acid reaction, and was of a light red color.

I do not doubt, gentlemen, that most of you have already determined from the history, that the patient has peritonitis, and a peritonitis due to a traumatic cause. And now the question arises whether this peritonitis is simply the result of a contusion of the walls of the peritoneal cavity, or whether some more serious injury has been done to the contents of the abdomen. Upon questioning the patient, and upon examination by palpation, it is found that the point of greatest pain and tenderness is to the right of the median line, and below the level of the umbilicus, that is, in the right iliac region, and it is found also that the force of the blow was received upon one side of the abdomen, and not directly in the median line.

Upon placing my hand over the abdomen, I not only find tenderness everywhere, but I get increased tenderness, and a sense of resistance to pressure and a dullness on percussion over the limited region I have described. It would seem, therefore, that the injury done, whatever it is, must have been inflicted upon some of the structures included between the median line and the ilium, and below the line of the umbilicus on the right side. In this region it is possible to conceive of an injury being inflicted upon a distended bladder, or upon the cæcum, or some portion of the intestines.

You remember that in the history it was said that although he was suffering intensely from pain caused by the blow, yet he was allowed to go home, and the evidences of a specially severe injury did not occur until after he got home, and these were the ordinary evidences of shock and prostration. He was brought here at the end of twelve hours after the injury, and was immedi-

ately put upon the opium treatment, and enough of the drug was given to him to relieve the pain. The progress of the case since has not been satisfactory, and this seems to make it more certain that the injury was of a more serious nature than a simple peritonitis from contusion, and that the force of the blow acted directly upon some of the abdominal viscera. Now I do not believe it was the bladder that was injured, because he had emptied it only three hours before the accident, so it could not then have been very full and distended. And besides, he has passed water since, which he could not have done if the bladder had been ruptured. He has not had any action from the bowels since he came in, and it has not been thought desirable to attempt to procure one, for there is no question as to the existence of intestinal obstruction here. I think it is possible that there has been a rupture either of the cæcum, the ascending colon, or some part of the small intestine, with an escape of its contents into the cavity of the peritoneum; and that explains the serious character of the peritonitis. From the rapid failure of the patient, and from the general character of the symptoms, I am therefore led to believe that we have here to deal with a peritonitis which is secondary to an injury of some abdominal organ. For if it were due to a simple contusion of the peritoneum, the prognosis would not be so serious.

I said that this man was put upon opium as soon as he came in. And this, as you know, has now become the classical treatment of peritonitis. It is a well recognized rule now, that the diagnosis of peritonitis being once established, you are to direct all your efforts to the controlling of the inflammation, and you are to wait until it has subsided before you attempt to treat the cause. This rule would not apply invariably to all such cases as come within the province of the surgeon, but it would apply to those cases where there is fecal obstruction, and a peritonitis depending upon a rupture of the intestines from typhlitis, typhoid fever, or other causes. The opium plan of treatment is now, I think, much more moderate in its application than it was when I was a student. Twenty-five years ago, when the plan of treating puerperal peritonitis by opium was first brought to the notice of the profession by Dr. Alonzo Clark, there was much interest excited; and there was a good opportunity for testing its efficacy, for there was about that time an epidemic of puerperal peritonitis, and there were many cases in the city. At that time opium was given in such large quantities that to watch its effects, the presence of a medical man of intelligence was rendered necessary, and so the physicians used to get medical students to come and sit by the bedside of the patient night and day, in order to watch the frequency of the respirations, which was the test by which the size of the dose was regulated. Dr. Clark was not satisfied with merely relieving pain and tenderness, but he thought it necessary to produce semi-narcotism. And it was found that there was an astonishing tolerance of this drug in patients suffering from this disease. For you could sometimes give them from a quarter of a grain to a grain of morphia every hour or two, and still keep them entirely conscious, but in a somnolent state, from which they could easily be

aroused. It was then thought safe to reduce the respirations to five or eight a minute if necessary. But I can tell you that, when you get a patient breathing only five times a minute, you had better proceed with some discretion. Yet I have seen the respirations reduced to seven in two minutes. But I can assure you that this is not a very pleasant condition of things to contemplate, especially if you have yourself administered the drug. Still, even with this amount of opium, the patient can be aroused and will answer questions intelligently. But accidents have occurred by carrying the narcotism so far, and I believe that most practitioners are now satisfied with a reduction of the respirations to twelve or fifteen a minute, and with simply making the patient comfortable; and for this purpose a much less quantity of opium is necessary. In most cases you need not give more than one grain every hour or two, and a safe plan is to begin with one grain every hour, and to repeat this dose until you get relief from pain, and after that to give it according to the necessity of the case. This patient has had fifty-eight minims of Magendie's solution since six o'clock this morning, that is, within nine hours and a half, which is equal to six minims, or one grain of opium per hour. His eyes are beginning to show the effect of the opium, for the pupils are considerably contracted, though not to pin-points by any means. He is also perspiring freely. One ounce of whisky per hour is being administered because of the rise of temperature. When you find this association of symptoms accompanied by a sudden rise of temperature you may be pretty certain of the result; for in peritonitis, as well as in cerebral diseases and apoplexy, a rise of temperature signifies that the end is approaching. Since this morning this man's temperature has run up from 101.4° to 104.2°, and his pulse is now 150 and respiration 15. Observe the characteristic position which the patient occupies, lying on his back, with his legs and thighs drawn up.

NOTES FROM THE PHILADELPHIA HOSPITAL.

Infantile Eczema.

Dr. W. H. Parish showed two cases. Both the children were apparently healthy, but were bottle fed, which was probably the cause of the eczema. This is an exceedingly troublesome disease to cure, and will oftentimes persist until you wish your patients were in Europe or in Florida. The scabs must be removed as fast as they form, and this can best be done by the aid of a starch poultice; when you remove it the scabs will come with it. To the raw surface apply benzoated oxide of zinc ointment; if there is much cutaneous irritation, dilute the ointment with $\frac{1}{4}$ vaseline. For chronic cases he uses an iodide of lead ointment, 10 grains to one ounce of cocoa butter. Internally, he will give Fowler's solution, one-half a drop thrice daily to a child aged seven months.

Deep Mammary Abscess.

Here was edema and swelling in the breast of a puerperal woman, who has had a chill. No fluctuation can be detected, but Dr. Parish will make an incision; for it will do no harm, even if there is no pus, and if there is, it will give it a vent and prevent it from burrowing. He did strike

pus, but had to go deep for it. There had been an escape of a few drops of pus from the nipple, which caused him to suspect its presence, in spite of the absence of fluctuation. The breast will be poulticed, and after the tenderness disappears he will strap it.

MEDICAL SOCIETIES.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated meeting, December 6, 1883. The President, R. A. Cleeman, M. D., in the chair.

Dr. W. Goodell exhibited two cysts of the parovarium, and remarked: Both patients got well; he indeed had never lost a patient from whom he had removed a parovarian cyst. In both cases a correct diagnosis was made previous to the operation. One interesting diagnostic point was the complete absence of the *facies ovariana*. The color in the cheeks was good, and the countenance was free from the anxious expression present in cases of ovarian tumor. One tumor had existed for ten years, the other for one. Another important point in the differential diagnosis is not only the flaccidity of the tumor, but its variable degrees of flaccidity. Upon inspection, it is seen to reach to the sternum, and seems to occupy a large portion of the abdominal cavity, but where the hands are placed upon its sternal edge, it can be compressed to the level of the umbilicus. An ovarian cyst on the contrary is hard and uncompressible. Exceptions to this rule are very rare, that is, either a tense parovarian cyst, or a flaccid ovarian one. A third important distinguishing point is the long time—ten years in one case—which the tumor existed, and further, without marked deterioration of health. After being tapped these tumors usually refill, but occasionally they do not, and a cure is thus brought about. The fluid withdrawn has been in every case limpid and generally colorless, but it has sometimes had in his experience an emerald tint. These tumors are generally free from serious adhesions, but if in an operation for the removal of one, adhesions should exist where for any reason their forcible separation would be unadvisable, or the cyst were intra-ligamentous, he would not hesitate to leave the adherent portion of the cyst-wall, or the whole cyst itself, after making a big hole in it, as the fluid it secretes is bland and unirritating to the peritoneum.

Any one examining one of these cysts for the first time would consider it to be of ovarian origin; for it is only by patient search that the ovary can be found spread out over the cyst-wall. The microscope will decide with certainty in any other-wise doubtful case. The tumor is covered with a beautiful net-work of veins.

When a cyst of the parovarium exists on one side, the ovary of the opposite side is usually found to be diseased and should be removed. In these cases the remaining ovary was seen to be enlarged and the site of a small ruptured cyst was pointed out. The fallopian tube was also enlarged, and the terminal vesicle of the fallopian tube, or the hydatid of Morgagni was enlarged and cystic.

This hydatid sometimes attains the size of an orange, and often ruptures spontaneously without any bad effects. A few years ago one of these small cysts ruptured while he was making an examination of the patient to ascertain its character.

Dr. Goodell exhibited a

Cancerous Womb Removed per Vaginam.

In view of the very fatal statistics of the operation for the removal of the womb or the radical cure of uterine cancer, he had been unwilling to perform it. In most of the cases where the disease had been seen early enough by him to give a chance of success, the patient had been unwilling to take the risk. On one occasion, when every preparation had been made to operate, the patient had a convulsion, and an examination of the urine showed a high proportion of albumen, in consequence of which he refused to operate. About a month ago, Dr. Chas. W. Dulles called him in consultation to see a patient in whom the carcinomatous condition was limited to the anterior lip. The womb was movable. The case was put frankly before the patient, and all its dangers pointed out. The choice of them being given to her, she decided, after due consideration, to take the risks of the radical operation. The operation was not as difficult as he anticipated.

The first step in the operation was to scrape away all cancerous tissue and to sear the remaining surface with Paquelin's cautery. The vagina was then thoroughly cleansed. A stout thread was passed through the cervix, to draw down the womb, instead of using a volsellum, the handles of which would be in the way. A circular incision was made around the cervix, and the tissues were stripped up anteriorly and posteriorly to the reflection of the peritoneum, and laterally to the insertion of the broad ligaments. Finally, the peritoneum was opened, and the womb retroverted into the vagina by means of the obstetric crochet passed over the fundus. A strong thread was now passed through the body of the uterus, by means of which to manipulate it more easily. A ligature was now passed around the broad ligament of the right side and secured it *en masse*, and a second double ligature was passed through it and tied on opposite sides. This side of the broad ligament was then divided, the uterus drawn down and the ligament of the left side secured in a similar manner and divided. The vaginal wound was closed and dressed with iodoform and cotton. A frank peritonitis set in on the third day, and proved fatal on the fourth. The result made him doubtful whether the operation is ever justifiable; he, indeed, felt disposed to avoid it whenever possible.

Dr. E. E. Montgomery inquired about the feasibility of using the galvanic wire ecraseur to divide the broad ligament, keeping the wire at a low red heat and dividing the tissues slowly, and avoiding the necessity for a drainage tube. Another method which he had been revolving in his mind was by means of the galvanic knife to dissect out the uterus, leaving the peritoneum intact, thus imitating to a certain extent the operation of Dr. Marion Sims of scraping and the use of zinc chloride.

Dr. Goodell thought that Dr. Montgomery's galvanic wire would get too hot as the loop became small, and would then divide rapidly, like a knife,

and incur the danger of secondary hemorrhage. He fears that the steam generated by the hot wire would penetrate the peritoneal cavity and have an irritating effect. He has a galvanic cautery battery, but has not used it since the introduction of Paquelin's benzoline cautery, as he finds the latter far more handy and manageable. He thinks Dr. M.'s suggestion of shelling out the uterus a very good one.

Dr. Montgomery exhibited through the courtesy of Dr. W. H. Warder the

Uterine Appendages

which had been removed from a young lady for the relief of dysmenorrhœa which had resulted in physical and mental failure. Menstruation commenced at the age of fourteen years, had always been painful, and had developed hysterical manifestations. Bathing at the sea-shore had at one time stopped the periods for three months. After this her health failed. Her mind had been seriously affected for the last three years, and she would run away or do herself some violence at the menstrual periods if not closely watched. Examination: The uterus enlarged and tender; there was profuse leucorrhœa. The os uteri was dilated, and the uterine cavity scraped and cauterized with carbolic acid and bromides, etc., used internally, but no improvement resulted. The ovaries were removed to-day through abdominal section; cat-gut ligatures were used. The ovaries are very much enlarged, and contain small cysts. The abdominal wound was closed with silk sutures, and covered with an impervious dressing of collodion, cotton, etc.

Hystero-Epilepsy as a Complication of Pregnancy.

Dr. William H. Shipps, of Bordentown, N. J., sent the following contribution:

Briefly defined, hystero-epilepsy is a term applied to an abnormal neurotic condition in which are manifested certain phenomena, characteristic both of hysteria and epilepsy. Out of 276 patients confined at La Salpêtrière Hospital, Paris, under treatment for various nervous affections, 32 were diagnosed by Beau, a careful observer, as suffering from this disease. Among this number, the malady assumed either a distinct or combined form, hence he very wisely groups the cases in two classes. In the first, the hysterical seizures and epileptic fits remain distinct, one from the other; to this form he adapts the term given by Landouzy, and designates it as hystero-epilepsy with distinct crises.

In the second class, and the one of which this article furnishes an illustration, the hysterical and epileptic seizures are co-eval, both developing at the same time; to this form the name of hystero-epilepsy with combined crises has been given. The object of this paper is, not to enter into a consideration of the disease as it is met with in general practice, but simply to examine it as a complication of pregnancy, a standpoint from which, fortunately, we are rarely called to view it.

During the early part of March, 1883, I was called to attend a woman said to be in a fit. Arriving at the house, I found, lying on a bed, a young woman, apparently seventeen or eighteen years of age, of fairly vigorous physique, who was striving against the united efforts of two or three neighbors, who sought to prevent her doing

herself bodily harm in the violence of her struggles. Examination showed entire loss of consciousness, eyes open and staring, pupils widely dilated, frothing at the mouth, which was then tightly closed, pulse full and bounding. Inquiry elicited that during the day she had been visiting a friend, herself the subject of some spasmodic affection, and whilst in her company became greatly exercised on some trivial occurrence, and in this state of excitement returned home, which place she no sooner reached than she was seized with a convulsion. Her husband informed me that she was in the third month of pregnancy, and that prior to this morning she had on one or two occasions attacks somewhat similar though of less severity. I at once injected, hypodermatically, one-third grain of morphine, which in a short time was followed by a total disappearance of all spasmodic action, a state of stupor supervening, from which, in the course of three or four hours, she aroused, apparently as well as ever. On the day following I was called to see her, and found her in a state of high nervous excitement, sobbing and deploring the presence of some impending danger, which she, in her imagination, insisted was threatening her. In a short time, the stage of muscular contraction, loss of consciousness, stupor, etc., took the place of hysterical symptoms, finally terminating as before in a return to her normal condition.

Without attempting to follow the case step by step, taking in all its details and noting the many and peculiar phases through which it passed, it is interesting to note that prior to September 23, '83, covering a period of two hundred days, not a day passed without the occurrence of one or more paroxysms. At times the hysterical phenomena would be most marked and usher in the attack; then again, the epileptic fit would take the precedence; always, however, accompanied by the undeniable imprint of the dual disease, hystero-epilepsy. In the inter-paroxysmal period she enjoyed for the most part average good health.

On the morning of September 23d, I was asked to see her in an attack of more than usual gravity. When I reached the house she was profoundly unconscious, and had been so for several hours. The time for her approaching labor being near, I made a vaginal examination, but found no evidence of commencing uterine action. I ordered a hot mustard bath, mustard to the extremities, and

bromides the moment she should be able to swallow. In the evening when I again called, her condition was apparently unchanged. I then ordered a blister to the nape of the neck, and left the patient, to return early in the morning. At 7 a. m. a messenger called stating that the woman was now perfectly rational, and to all appearances in labor. I at once responded, and found that she was having bearing-down pains of moderate intensity at intervals of five or ten minutes, mouth of womb dilating, vertex presenting. I remained by the woman's side until 3.45 p. m., when the child, a healthy female weighing 9 or 10 pounds, was born. The labor did not differ from ordinary labors, except that it was only by the utmost vigilance that the woman was prevented from falling into one of her accustomed attacks. After the birth of the child, I gave it to the mother, at the same remarking to her, that as she valued the life of the child, under no circumstances to allow herself to have another convulsion. She promised faithful obedience, and up to the present has not shown the first indication of her old trouble. It should be mentioned that during the entire period the patient was under observation she had daily taken large doses of the bromides and other nervines without any effect, save perhaps in ameliorating the number and violence of the paroxysms. The case is interesting on account of the rarity of the disease as a complication of pregnancy; its persistence throughout the entire period; its resistance to all remedial measures, and the final disappearance of all symptoms after the termination of labor.

Two queries very naturally present themselves: What was the exciting cause of the attacks? Would the induction of premature labor in this and similar cases be justifiable?

In answer to the first query, I attribute the attacks to an action upon the brain and spinal cord, reflex in its nature, and developed or excited by the fœtus in utero.

The happy termination of the case would seemingly offer a negative to the second query; but better judgment will, I think, suggest the wisdom of the operation and the danger of refusing to employ what, theoretically at least, offers the only chance of relief; at all events, in a similar case I would most certainly have recourse to the operation, and expect from it the best results.

EDITORIAL DEPARTMENT.

PERISCOPE.

A New Anæsthetic Mixture.

Dr. William A. Byrd, of Quincy, Ill., has been using a mixture, composed, by measure, of bromide of ethyl, one part; chloroform, three parts; alcohol, four parts. These substances, mixed, form a clear solution, of a pleasant odor, and of a warm, sweetish taste. Dr. Charles Wesley Rook

thus writes of its physiological action in the *Jour. Am. Med. Association*, December 15, 1883: I have administered this anæsthetic to a number of patients, varying in age from early childhood to adult life; to those enfeebled by disease or suffering, and to those apparently healthy; for operations comparatively trivial, and for others which were protracted and serious; inducing and sustaining complete anæsthesia, in some cases only for a few moments, while in others for more than

an hour; and in all these cases, with their varying circumstances and conditions, I have observed a remarkable similarity in the physiological actions of this anæsthetic. The stage of excitement or intoxication is brief, sometimes absent; if occurring, is never violent. The stage of spasmodic rigidity of the voluntary muscles seldom occurs; when occurring, it is not extreme. Following these stages, when they are present, or within a few minutes from the commencement of the inhalation, the stage of complete anæsthesia is induced, when any unfavorable or alarming conditions or symptoms occurring in the preceding stages, as excitement or rigidity, will be relieved, so that the vital functions are carried on as regularly, and apparently as effectually, as if the patient was in a natural physiological sleep.

The time required to produce complete anæsthesia is from one to three minutes in children, and from three to five, and possibly eight minutes in adults. When inhaled, and especially if inhaled through the nostrils, patients will sometimes complain of a choking or suffocating feeling, probably due to some spasmodic condition of the glottis or larynx, which is quickly relieved by requesting the patient to inhale through the mouth, three or four deep inspirations. Sometimes, though very seldom, coughing will be caused, perhaps due to the action of the anæsthetic vapor upon the over-sensitive bronchial mucous membrane, but it is quickly checked by pushing the anæsthetic a little more rapidly. Nausea and vomiting may occur, more apt to when administered soon after eating, and, like coughing, may be checked by crowding the anæsthetic a little faster.

Effect upon the Eyes.—Soon after the inhalation is begun, and especially if the stage of excitement is present, the pupils are dilated, but when complete anæsthesia is induced, they are more or less contracted; the conjunctiva is usually insensible to irritation, but I have seen a case in which the degree of anæsthesia was sufficient to admit of the thorough and extensive application of the actual cautery, and yet the conjunctivæ remained sensitive, and the pupils responded quickly to light.

Effect upon the Circulation.—At the commencement of the inhalation, the pulse, either from excitement or in anticipation of the coming operation, would naturally be somewhat quickened; but when complete anæsthesia is induced, the pulse becomes slower, fuller, and stronger.

Effect upon the Respiration.—This is at first stimulated, but when insensibility is induced it becomes slower and more regular, very much resembling the respiration of natural sleep.

Effect upon the Temperature.—It is generally lowered more or less, as the skin is usually moist, and occasionally free perspiration occurs.

During the stage of complete anæsthesia, the eyelids are closed, the face retains its natural color, so that the countenance looks peaceful and placid.

The duration of the stage of anæsthesia is variable; in some, complete consciousness returns within a few minutes after the administration is discontinued, while in others the stage of anæsthesia seems to be followed, without any intermission, by a period of natural sleep, which may

continue from ten to thirty minutes, or even longer, from which, on awakening, the patients seldom have any symptoms referable to the anæsthetic.

In the preparation of this anæsthetic, it is believed that no new chemical compound is produced; that the ingredients, not entering into a chemical union, simply form a mixture. The alcohol was added as a diluent or vehicle for the better administration of the chloroform and ethyl bromide. Although alcohol, alone, is employed by some, more especially by Dr. John D. Link, of Terre Haute, Indiana, but little of the virtues of this anæsthetic, except, perhaps, the sleep following the stage of complete anæsthesia, are attributed to the alcohol.

ADMINISTRATION.

Because of the quantity of chloroform entering into its composition, a considerable amount of atmospheric air should be inhaled along with the anæsthetic. It has been administered most frequently through an inhaler—Dr. Jos. C. Hutchinson's, of Brooklyn, N. Y. But the same results have been obtained when simply a towel was used as an inhaler. At the present date, November 30, 1883, anæsthesia has been produced in ninety-eight cases, without causing any bad effects, save vomiting in three cases. The quantity necessary to induce and sustain anæsthesia, depends, of course, upon the duration of the operation. A half drachm poured into the inhaler, or upon a towel, will generally be sufficient to induce anæsthesia, which may be sustained by the addition, from time to time, of half the former quantity.

The Etiology of Fungous Endometritis.

The *Med. Times and Gaz.*, December 8, 1883, says:

A recent number of the *Archiv für Gynäkologie* contains a long, but somewhat theoretical, paper by Dr. Brennecke on the etiology of fungous endometritis, more especially of the form described by Olshausen under the name of "chronic hyperplastic endometritis." The weakness of this carefully written paper is in the small number of cases upon which it is based. Of the disease described by Olshausen, the author believes there are two forms—a glandular, in which overgrowth of gland-tissue is the conspicuous change; and an interstitial, marked by hyperplasia of the connective tissue. Between these extreme forms, other mixed or intermediate cases occur, in which both changes are present. The interstitial form occurs in the younger, the glandular form in the older patients. Dr. Brennecke describes six cases observed by himself, and refers to some other published cases, and upon this material he builds his theory. He finds that in them all the hemorrhage and other symptoms characteristic of the disease were preceded by periods either of complete amenorrhœa, or of irregular, infrequent, and scanty menstruation. Therefore, he says, the disease depends primarily upon a functional disturbance in the ovaries, which, as a reflex effect, causes chronic hyperæmia of the uterine mucous membrane, and thus leads to hypertrophy of that structure. This reflex effect is produced through the nervous mechanism which governs ordinary

menstruation, and it therefore affects the body only, not the cervix, of the uterus. Being a disease due to reflex action, it cannot be cured while the cause of the reflex effect remains in operation. Hence, says Dr. Brennecke, the frequency of relapse which is observed in this disease. Our author also adduces the occasional association of abscess of the ovary with this morbid condition in support of his view. For the treatment of this form he looks on the curette, used to remove the hypertrophied membrane, as the grand agent. This should be combined with tonic medication to alter the morbid action which leads to its formation. Cauterization he thinks useless, its adoption being based on an erroneous view as to the pathology of the disease, viz., that it is merely a local change in the uterine mucous membrane. He does not think that this malady ever passes into cancer. The form of disease in which there are localized fungous outgrowths in the uterine cavity, Dr. Brennecke in his experience has always found dependent on some other disease of the uterus: either chronic catarrh (simple or gonorrhœal), retroflexion, stenosis of the os internum or externum, interstitial or submucous fibroids. This form he therefore calls the local uterine form, in contradistinction to the cases of chronic hyperplastic endometritis, which, in accordance with his theory, he calls the ovarian form. He points out these distinctions:

1. In the uterine form there is hemorrhage from the beginning; in the ovarian, menstruation is at first deficient or absent.

2. In the uterine form there is scarcely any tendency to relapse; in the ovarian, a strong tendency.

3. The fragments removed by the curette are smaller in the uterine form than in the ovarian.

4. In the ovarian form these pieces show the structure simply of hypertrophied mucous membrane; this being seldom the case in the uterine form, in which the products of catarrh and ulceration are commonly found.

Lastly, Dr. Brennecke describes fungous endometritis following abortion, which he denominates the decidual form. These cases yield the most satisfactory results to treatment, being commonly completely cured by once using the curette. Dr. Brennecke adds to his paper an interesting novelty in the shape of a plate, in which the course of some cases of fungous endometritis is shown in a graphic form.

The Treatment of Acute Meningitis.

Dr. William T. Plant publishes a lecture on this subject in the *N. Y. Med. Jour.*, December 22, 1883, in the course of which the following occurs:

"If you are clever enough to recognize the disease at its invasion, there is a little hope. The child should be kept quiet in a darkened room, and spared all occasion of annoyance and fretfulness. The diet should be as nutritious as the patient will take. Milk, cream, and meat broths are best. A hot foot-bath fortified with mustard lessens the cerebral congestion and soothes the child. I would use it as many as four or five times in the twenty-four hours. Keep the feet and legs warm by bottles of hot water, or other means.

"Both reason and experience favor cold appli-

cations to the head. If there is a heavy growth of hair, it should be thinned, and cloths, not too thick, wrung from iced water and changed often so as to make constant impression of cold, may be laid upon the head. When there is intense heat of head, bladders of pounded ice may be applied. This is a powerfully depressing measure, and should not, I think, be used in infants or weakly children. When employed, some layers of cloth should come between the ice and the scalp.

"Correct constipation by an agreeable laxative, but be chary of much physic, for the chance of success is not made better, but rather the worse, by hypercatharsis.

"About the only drug that seems to have anything in its favor as making for recovery is iodide of potassium. Roeser suggested it in 1840. It has been extensively used since then with occasional benefit, or apparently so. Quite a number of cases of recovery under it, but discouragingly few as compared with the whole number of cases, have been reported from entirely trustworthy sources. It should be early and continuously given in doses of from two to five grains. To relieve the headache and ward off convulsions, bromide of potassium is our best remedy. When there are extreme restlessness and discomfort, you will find it of service to combine chloral and bromide. Ordinary doses will often fail of appreciable effect. Give them boldly until your purpose in giving them is effected. Valerian, in fluid extract or other form, tends to quiet the muscular twitching and the general restlessness. In most cases it is better to dispense with opiates, since they increase cerebral fullness, constipation, and the growing tendency to stupor. But in certain cases the agony is so great that they may, and should, be freely used, even hypodermically.

By the early and persistent employment of such means as these you may possibly save your patient, and then, in your surprise, you will ask yourself whether, after all, your diagnosis was not erroneous.

The prophylactic treatment of tubercular meningitis promises more than the direct. To prevent so terrific a malady is better than to cure it, even if we could cure it. A child with inherited tuberculous or scrofulous tendencies should be well looked after, especially if it begins to exhibit those vague but growing evidences of poorliness that are so often precursory to this affection. Cod-liver oil should be given, a half-teaspoonful or more ter die. The diet should be nutritious—the best that can be digested. Stimulants are in order—Bourbon or brandy with milk. Mild exercises out of doors, that interest and amuse without fatiguing, should be provided. Change of air and scene is often of signal service. If there are moist eruptions about the head and face, I would not attempt to dry them by local applications, but rather trust them to disappear with the improvement in the general condition.

Wax-like Disease of the Heart.

We note the following from the *Med. Times and Gaz.*, Dec. 8, 1883:

The heart has hitherto had the credit of escaping, as a rule, in cases of lardaceous disease; such, at least, is the opinion that will be gener-

ally found in our text-books, either expressed or implied. That distinction, however, it has no just title to, for Prof. Hamilton states (*Journal of Anatomy and Physiology*, October,) that, on examining cases of general waxy disease, he has found the heart to be affected in nearly every severe case, and sometimes when the affection is limited to a few organs. The change is one that would be very likely to escape detection by the naked eye, a slight milkiness of the endocardium in patches being the only appearance. The auricles are more prone to be affected than the ventricles, and the right more than the left. The wall of the ventricles is of a pale brown color; it is often atrophied, and but seldom hypertrophied. All these changes are, however, very slight; but the addition of iodine brings out rounded or irregular brown stains in the endocardium, and similar brown points may sometimes be seen in the substance of the heart-wall after the use of iodine. The pericardium is usually unaffected. Thus it appears that the disease in the heart corresponds to that found in the arteries, where, as is well known, the intima and middle coats are its chief seats. On examination under the microscope, after staining with methylaniline, the waxy material is found in the endocardium in irregular masses; it appears to have infiltrated the fibrous tissue of the endocardium, and to have pushed the fibres aside. These eventually become surrounded by the waxy material, but they do not become converted into it. The sub-endothelial fibrous tissue also contains many waxy deposits. In the myocardium also the waxy deposit occurs in small patches, either within a fasciculus of muscular fibres, or around the small arteries running in the perimysium externum. The waxy material is poured out from the capillaries into the spaces around these, between the perimysium internum and the muscular fibrils. As the quantity of waxy material increases, the fibrils become compressed, break down into a granular mass, and eventually are absorbed; in this way the fibres gradually undergo atrophy, the waxy matter growing more abundant all the time. It is to be especially noted that the fibres do not undergo any waxy degeneration themselves. The small arteries between the fasciculi are almost all waxy; the small veins, too, frequently become waxy; and many of the capillaries are similarly affected. Doubtless, now that attention has been called to the subject, the disease will be readily recognized by other observers; but if it be so frequently present as Prof. Hamilton believes it to be, it is a little remarkable that symptoms of cardiac failure should not form a more prominent feature at the close of life. It may be that more close investigation will demonstrate that such really is the case. At any rate, Prof. Hamilton has done good service in calling attention to a somewhat overlooked subject.

Tears of Blood.

In the *Brit. Med. Jour.*, December 8, 1883, we read:

This rare phenomenon, the reality of which has often been doubted, seems, however, to occur under certain circumstances. Damalix has published an interesting paper on this subject in the *Arch-*

ives d'Ophthalmologie. He was led to study it by the observation of a case in M. Panas's wards. The patient, a young hysterical girl, said that she had often noticed a flow of blood from her eyes, and spots of blood on her handkerchief after wiping them. For some time the hemorrhage occurred every night. A careful examination of the eyes showed nothing abnormal, but there were photophobia, facial neuralgia, and considerable blepharospasm. This case, as M. Damalix himself says, cannot be considered as conclusive, in spite of the probable veracity of the girl and her parents, as the hemorrhage was never seen by him. But there are on record some observations which do not leave room for doubt. In a case of Hauser, and in another of M. Brun, the observer could actually see the blood flowing from the eyes like tears; there was no possibility of trickery, and microscopical examination of the fluid showed that it was really blood. As for the diagnosis, the name blood-tears must not be applied to the various forms of hemorrhage caused by some organic lesion of the mucous membrane, such as small polypi, etc. The true form has nothing to do with any visible lesion, and the course of the accidents is remarkably irregular. Sometimes there are no premonitory signs, the blood appearing without effort or pain; in other cases, the patient feels for some time pain in the forehead, or at the root of the nose, or, it may be, a feeling of tickling and heat in the lids, which disappears when the blood begins to flow. The amount of blood lost varies from a few drops to a wineglassful; the flow never lasts more than a few minutes, is always intermittent, and generally coincides with other hemorrhages in the skin or mucous membranes, or, on the contrary, with *suppression mensium*. A study of the etiology of the disease shows that it is most frequent in hysterical women suffering from anæmia or hemophilia.

Globulinuria in Acute Bright's Disease.

The *Lancet*, December 8, 1883, says:

A case of acute nephritis is reported by Herr Werner, of Heidelberg, as occurring in Professor Dusch's clinic, which is probably unique. It was that of a child, aged five years and a half, who developed symptoms of the disease after exposure to wet, five days before his admission into hospital. There was only a little oedema of the eyelids, together with signs of diffuse bronchial catarrh on admission; but general dropsy rapidly supervened, and death occurred from suppression of urine five days afterwards. What renders the case remarkable was that the urine only contained globulin, and never serum-albumen, although repeatedly examined, amongst others by Kühne. The characters of the urine were its high color, cloudiness, and moderate deposit, but no blood. Slight turbidity appeared on boiling with nitric acid, and also with acetic acid, clearing up on excess; and after supersaturation with magnesium sulphate no precipitate was obtained in the filtrate on the addition of nitric acid. Fatty epithelial and granular casts were found. The writer points out that hitherto globulin has never been met with in urine unless in company with serum-albumen; and quotes the statement of Senator to the effect that the quantity of globulin is most in the amyloid

form of renal disease, next most abundant in acute nephritis, and least in the chronic diffuse form, although much albuminuria may be present. The same author also suggested that the globulin may be derived not only from the blood, but also from the morbid changes undergone by the renal epithelium, and Herr Werner thinks his case proves the possibility of its being solely derived from the latter source. He interprets his case, then, as one in which the renal epithelium was principally affected, which speedily and widely fell into a necrotic condition, as evidenced by the tube casts, and that this necrotic cell protoplasm was the source of the globulin. The idea is, to say the least, ingenious; and it is most unfortunate that no post-mortem examination was obtainable. It should be added that the child had previously been in good health, and had never had scarlet fever.

The Variations of Pulse-wave Velocity.

Dr. A. T. Keyt, of Cincinnati, contributes a very valuable and elaborate paper on this subject to the *Jour. Am. Med. Ass.*, December 1 and 15, which thus concludes:

From this study we deduce the following resumé of the more prominent facts:

1. The velocity of the pulse-wave is determined above all by inherent states of arterial elasticity; being slower as the arteries are more elastic.

2. It is incessantly changing, within small limits, in consequence of variation of arterial tone; being faster as the tone is higher.

3. It diminishes with the size of the artery traversed.

4. It tends to increase with increase of arterial pressure, but modification from variation of pressure often fails to be manifest.

5. It is not perceptibly modified below the site of an arterial obstruction, but the distal wave is delayed there in consequence of check at the site of obstruction.

6. It is not perceptibly modified in an artery below the site of an aneurism, although the distal wave may be delayed there in consequence of absorption by the yielding aneurismal walls.

Pipitzahzoic Acid.

At a meeting of the German Apotheker-Verein this year, at Wiesbaden, Apotheker Vigener, of Biebrich, read a paper on a new drug from Mexico, called by the natives there "Pipitzahuatle," and an acid obtained from it—pipitzahzoic acid.

The author states that the roots of the plant in question, which belongs to a genus of the natural order of Composite not known in Europe, are used by the natives as an excellent and safe purgative. The plant and the acid obtained from it were briefly described in the *Annalen der Chemie* in 1855, but since then nothing more has been written on the subject.

M. Vigener prepares the acid from the root of the plant by adding boiling distilled water to a strong tincture of it until precipitation takes place. The whole is then allowed to cool, and the crystals of the acid are dissolved in cold alcohol, and purified by sublimation from a water-bath, the temperature at which sublimation takes place being 90° C. According to M. Vigener, pipitzahzoic

acid is an anthrachinone. Alkalies and the alkaline carbonates produce in its solution a coloration resembling that of solutions of potassium permanganate. Pipitzahzoic acid has also received the name of "aurum vegetabile."

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—A fresh and suggestive pamphlet of sixty odd pages on the lenses of the eye, and the methods of studying them, has been written by Dr. Severin Robinské, of Berlin. He criticises the means hitherto employed, gives directions for the study of fresh preparations, describes some new methods of his own, and has some valuable observations on the so-called lense-fibres. (*Zur Kenntniss der Augenlinse und deren Untersuchungs-methoden.* Berlin, Verlag von Eugen Grosser.)

—Among new investigations into the mysterious realm of psychical manifestations, the mental relationship of diseases is always a question of the first order. This is appreciated by Dr. C. H. Hughes, of St. Louis, who has recently contributed a valuable study in this connection on the frequent association of glycosuria and melancholia. We quote his conclusion in his own words: "There is an intimate relationship between nervous depression and glycosuria. The influence of agencies that conserve, recuperate and tranquilize the nervous energies tend to prove this, such as the bromides, chloral, opium and galvanism, the latter especially, when applied to the occipital regions."

—Cupples, Aphon & Co. are working hard on a new edition of Dr. Francis H. Brown's "Medical Register for New England." The work will contain much new information, and will be issued at a lower rate than in previous years, and no doubt every doctor of New England will avail himself of a manual so essential in his profession.

—A neat report, making a pamphlet of forty-eight pages, of the last meeting of the American Dermatological Association, has been prepared by the Secretary, Dr. Arthur Van Harlingen. It contains excellent abstracts of the numerous well-prepared papers read before the Association. It may be obtained from the Secretary, at Philadelphia.

—It would be a pity to see the *Index Medicus* discontinued. But it looks as if there is scarcely interest enough in it to pay actual costs of publi-

cation. The publisher, M. F. Leypoldt, 32 Park Row, New York, makes an appeal to the profession to come to his assistance in the matter, and we hope he will have a favorable hearing. It is a highly creditable piece of work, and ought to be supported.

—Dr. Matthew D. Mann, of Buffalo, N. Y., has sent us pamphlets describing a series of twelve ovariectomies and surgical operations on the pelvic organs of pregnant women. They are able contributions to gynecologic science.

—The cold douche in fever is highly vaunted by some and equally deprecated by others. Dr. G. C. Smythe sensibly discusses the subject in a reprint from the *Cincinnati Lancet and Clinic*, October 6, 1883, entitled, "The Antipyretic Treatment of Typhoid Fever."

BOOK NOTICES.

Wiesen, as a Health Resort in Early Phthisis, with Directions for Clothing, Diet, and Exercise in the Swiss Alps during Winter. By A. T. Tucker Wise, M. D., etc. London: Bailliere & Co., 1883.

The advantage in phthisical cases of a high, dry, generally clear climate, although it may be a cold one, is now generally conceded. Several locations in the upper Alps have long enjoyed celebrity as winter resorts. Among them, Davos-am-Platz stands pre-eminent, but doubtless there are many other stations just as good, though less known. One of them is Wiesen, a hamlet 24 miles from Chur, 5,000 feet above the level of the sea, which Dr. Wise introduces to us in the above volume. We should judge it to be a favorably-situated cure, possessing some advantages over Davos.

The general hygienic and sanitary advice in the volume is instructive and sound. The author brings into relief the stimulating, tonic properties of cold with emphasis. He makes a statement which we have not found any other Englishman willing to acknowledge, to wit: That the Anglo-Saxon race in the Northern United States of America "is physically superior and more vigorous than that of the parent stock." A map, and ample meteorological tables, accompany the text.

Sepulture, Its History, Methods, and Sanitary Requisites. By Stephen Wickes, A. M., M. D., Philadelphia. P. Blakiston, Son & Co. Cloth, 8vo., pp. 156.

The disposition of the dead has become one of the leading questions in the sanitary economies of

modern life. In the closely settled countries of Europe it has become even serious, and it is not long to look ahead before the same will be the case in the older States of our Union.

The various methods which have been adopted to this end by various peoples and in various ages are passed in review in the volume before us. The customs of the Greeks, Romans, Persians, early Christians, etc., are described, and their appropriateness discussed. The author then passes to a hygienic discussion of the evils arising from sepulture where it is carried on with indifference to sanitation. The virulence of several diseases is traced to animal putrescence, and the rules laid down which should govern the management of cemeteries. The author does not discuss cremation, as he thinks there is no call for that method of disposing of bodies.

A Treatise on Syphilis of New-born Children and Infants at the Breast. By P. Diday. Translated by G. Whitely, M. D., with notes by F. R. Sturgis, M. D. New York, Wm. Wood & Co.

For many years Prof. Diday was the leading authority on syphilis of provincial France. His studies were directed very largely to hereditary forms of the disease, and the present treatise was long a standard on the subject. Somewhat out of date now, the notes and additions of Dr. Sturgis serve to bring its teachings up to the position of syphilology at present. The volume is a member of Wood's Library of Standard Medical Authors.

A Treatise on Bright's Disease of the Kidneys. By Henry B. Millard, M. D. 8vo., cloth, pp. 246. N. Y. Wm. Wood & Co.

It is rare that we find a book so evidently the result of careful, original study, so fresh from the bedside, we may say, as the one before us. Retaining, for reasons which he states, and which are sound, the general term "Bright's disease," the author includes in his study the various forms of nephritis, which, since the days of Dr. Bright, have been recognized as simple, acute and chronic, interstitial, croupous, and suppurative. The diagnosis of these forms, always puzzling to the inexperienced, and sometimes to the experienced, is set forth with clearness. Pathological questions are discussed without that pedantic parade of neologisms in which many, especially German authors, are prone to indulge. The anatomy of the kidney, the tests for albumen (which Dr. Millard prefers to write albumin), its significance, and that of urinary casts, etc., are treated with a free style which betokens familiar acquaintance. A number of illustrations are inserted, all or nearly all original.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

CEREBRAL SYPHILIS.

It is of the utmost importance that physicians should have a clear and definite idea of the nature of this form of syphilis, and should have the matter constantly in mind; for it is an exceedingly insidious and dangerous affection if not early recognized, yet very amenable to proper treatment.

Of its nature, Dr. H. C. Wood tells us, in a lecture in the *Boston Medical and Surgical Journal*, December 20, that it consists essentially in an inflammation of the brain or of its membranes, generally of the latter, or of a tumor thereof.

Its symptoms, as we would presume, are those of any inflammation or tumor of this region, there being no special, characteristic symptoms of the disease.

In this fact lies the difficulty, and at the same time the necessity of recognizing the cause, as the treatment will be so radically different.

A peculiar and misleading fact is that cerebral syphilis usually occurs where the evidences of original infection have been very slight—where the patient has probably had a gonorrhœa, and a concealed chancre, with very slight, scarcely noticeable, secondary manifestations. The disease will not develop, as a rule, for years (ten to forty), after the original infection, when the patient may be suddenly seized with cerebral manifestations and die in a day or two.

Abnormal somnolence should call our attention to syphilis, as it is very often the most prominent symptom of cerebral syphilis, although occasionally the very reverse will obtain, namely, wakefulness.

Basal growths not tuberculous, paralyzing the oculo-motor and other nerves supplying the eye, are rarely anything else but syphilitic. Syphilitic basal growths are very frequent. Remember, then, that centric squint, dilatation of the pupil, ptosis, and paralysis of the ocular muscles, are in an adult almost certain evidences of cerebral syphilis.

Sudden nerve attacks, such as temporary aphasia, deafness, epileptiform attacks, sudden and temporary loss of power in a limb, numbness

and the like, are oftentimes due to syphilis. The important fact to be remembered is that these inexplicable, sudden, varying, temporary nerve attacks, when not dependent on hysteria, are very characteristic of cerebral syphilis. They are dependent on the fact that cerebral syphilis is prone to develop with great rapidity after a period of latency, and to cause sudden and violent congestions in proximity to the tumor.

To condense Dr. Wood's most interesting lecture into a brief summary, we would say that whenever we have offered to us the symptoms of cerebral inflammation or tumor, the thought should enter our minds that syphilis *may* be the cause; and realizing how exceedingly difficult it oftentimes is to elicit the truth from this class of patients, especially if they happen to be the sedate and respectable fathers of families and prominent citizens, we should carefully feel our way to fathom the case. If we have any reasonable assurance that syphilis may have been about at any time, then we must institute appropriate treatment; if not, and our other remedies fail to produce any effect, then would we, ourselves, not hesitate to proceed cautiously with specific medication, the results of which would soon settle the question.

A leader of the profession has said that in his opinion the whole world is becoming gradually syphilized; in other words, that by the influence of inheritance and infection the disease is reaching out in every direction. Whether this distinguished man's view is literally true, we would hesitate to say; but we do know that the influence of syphilis on diseased conditions, that is that the peculiar morbid state (whatever it may be) that is produced in its typical entirety by impure sexual intercourse, and modified in various ways, notably by time and medication, is exceedingly universal, and that its effects are noted in men and women to whom the imputation of impure, *illicit* intercourse, would seem to be, and in many cases would really be, most preposterous.

Knowing this, and knowing from so high an authority as Dr. Wood that syphilis is so potent a

cause of cerebral disorder, we would say, be on the lookout for it and be ready to combat it.

OUR FUTURE WATER SUPPLY.

The recommendation of chief engineer of the water department Ludlow, in reference to our water supply, is an eminently practicable one, and well worthy of being carried to a successful consummation.

Those of us who have visited Rome, have oftentimes stood and gazed at the stone giants striding the lonely Campagna, bearing mute evidence to the civilization and sanitary refinement of the Rome of two centuries and a half ago, as do the pyramids and the sphynx to the wonderful engineering skill of ancient Egypt; for, in these ruins, we read that Rome thoroughly realized the advantages of supplying her citizens with pure and wholesome water, and that in order to secure it, she was willing to go to the enormous expense of building vast aqueducts to bring to the city water from the far-off mountains, pure and fresh, and uncontaminated with human refuse.

Such is practically the idea suggested by Colonel Ludlow, and such should be the system in vogue in all large cities.

The water supply of this large city, with a population of 1,000,000, is derived from a river, lined on either bank with goodly sized manufacturing villages, from which human and mill refuse flow into it, these villages coming as near Philadelphia as three miles, while still nearer, a large cemetery, on a high bluff, sends all its rotten drainage into our drinking water. A short time since, our water became so notoriously bad, that an intercepting sewer, at a cost of over \$500,000, was built, in order to carry the waste of these towns down along the river bank, and empty it at a point below that from which our water was derived.

This cost a great deal of money, and yet, to the mind of any one conversant with the sanitary needs of our city or any large city, it seems evident that it is only money wasted; for it is but

trifling with a great public necessity, the demand for pure and wholesome water.

Our public buildings have already cost millions, yet they are not really necessities, for our public affairs can be satisfactorily carried on in a much less pretentious edifice; but pure water is a necessity, we all recognize it as such, and yet we tamely submit to this disgraceful state of affairs, and go on daily drinking liquid sewage, while enough money is annually wasted, to erect in a few years an aqueduct that would ensure us for all time a plentiful supply of water, from a source that would be absolutely beyond the possibility of contamination.

There is no use in wasting words about such self-evident matters.

We should learn from the experience of others, and act promptly.

We venture to say that had Rome derived its water supply from the Tiber, it never would have conquered the world; for instead of being a nation of warriors, of heroes, and of *men*, it would have been a country of sickly and effeminate dudes, poisoned and debased physically, morally and mentally, by drinking its own and its neighbors' waste.

This is a proposition founded on fact, and no one conversant with sanitation will even attempt to refute it.

The greatest problem for all large cities is the water supply; and in order to have it good, it must be derived from a distance, from a point where human refuse *cannot possibly pollute it*.

AN INSULT TO THE PROFESSION.

A deliberate attempt on the part of any commercial company to belittle and disparage the medical profession should be met with determined resistance by the profession; and such a company should be made to feel that nothing can be gained pecuniarily by action of that kind.

This has been done by an important Atlantic Carrying Company, and has been continued after repeated and urgent, though always respectful, protests have been made it by numbers of physicians. The company we refer to is the Red Star

Line Atlantic Steamship Company, sailing between Antwerp in Europe and Philadelphia and New York in the United States—Peter Wright & Sons, agents in the last-mentioned cities. Through sailing under the Belgian flag, its ships are mainly owned by American capitalists, and most of its officers are Americans.

Its action which we protest against is briefly as follows: All passenger steamers are obliged by law to carry medical officers—ship surgeons. In every line except the above, the surgeons are assigned quarters and mess with the first-class passengers. Both as members of a learned profession, as officers, and by custom, they are justly entitled to this. Within the last year the Red Star Line has ordered its surgeons to mess at the second-class table, and ranks them in other respects as second-class passengers. This is an indignity which has been keenly felt as such by all its medical officers; some have resigned in consequence, others have waited, trusting that the remonstrances of members of the profession to the company would have some effect. So far from this, the Red Star Line has added another insult to the profession, by passing over its protests with contemptuous silence.

The appeal is now made to the medical editors of the United States, to our Medical Societies, and to physicians individually, to unite in forcing this company to respect the profession of their medical officers, and to place them on an equality with the first-class passengers. Until this is done, we trust that every physician will not only refrain himself from selecting this line, but will recommend others in its place. The niggardliness which must be its motive in thus insulting the profession cannot fail to show itself elsewhere, to the detriment of the line. There are plenty of other lines, just as cheap, just as safe, in many respects more pleasant and better appointed than the Red Star Line, and they do not put their medical officers in a position wounding to their self-respect and derogatory to the proper rights of the profession. We ask the attention of all to this matter, as one which touches the interest of all.

ERGOTISM.

Since poisoning by ergot may occur at any time in the practice of the country physician, it is well that we should know how to recognize it. The epidemics that have occurred off and on in Germany since 1879 have afforded ample opportunity to Menche, of Bonn, to study the disease, and we note the following symptoms from his report in the *Deutsch. Arch. f. Klin. Med.*: He noted 500 cases. Like with all other morbid agencies, the weakly were more quickly affected than the strong. The first symptom was itching of the hands and feet, sometimes general, and it was the last to disappear. Soon comes on the spasmodic stage, characterized by a claw-like position of the fingers, with the thumb strongly flexed. At times, nearly every muscle in the body was affected, producing rectal and vesical tenesmus, dyspnoea, precordial pain and diaphragmatic cramps. These attacks varied in duration and in frequency of recurrence. The disease was usually preceded by a prodromal stage of malaise, headache, weakness, vertigo, and usually loss of appetite, though sometimes the patients were very hungry.

In the severe cases, epileptic attacks sometimes occurred; and in the milder cases relapses were frequent, while convalescence was always slow.

A singular and noteworthy fact was that abortion was not produced in pregnant women.

When such a combination of rather peculiar symptoms offer themselves to observation, it will be well to look into the grain that may be in use. The treatment will, of course, consist in the removal of the cause.

NOTES AND COMMENTS.

The Influence of Syphilis Upon the Progress of Cancer.

We note the following by Prof. Verneuil from the *St. Louis Med. and Surg. Jour.*, December, 1883:

The reciprocal influences of diatheses are not well known yet, from want of attention being drawn in that direction. That of syphilis upon cancer can, in certain cases, be given with precision, of which the following cases are examples: A woman, whose antecedents are unknown, was taken with a cancerous tumor of the breast, about

a year ago. The progress was at first very slow, but she contracted syphilis eight months since, which is now in the full period of secondary accidents. On investigation how the syphilis had acted on the cancer, the conviction is reached that it has considerably augmented its progress and its generalization. Indeed, the entire left breast and the axillary ganglia have undergone a cancerous degeneration. The subclavian ganglia form a considerable mass, and reach up to the mastoid apophysis. Considering that the first notion of cancer is of one year only, and that it attained its present development in the last few months; that the invasion of the subclavian ganglia is only exceptional, and then it is considered a formal contra-indication of all operative interference; the conclusion is inevitable, that syphilis was the origin of this abnormal process. This case presents another unusual fact. When cancer is largely developed, and the ganglia are affected, pain is always very great; but in this case, the patient does not suffer any pain at all.

Double Colle's Fracture.

It is very rare to hear of such a case as that reported by Dr. R. J. Bryden (*Brit. Med. Jour.*, December 8, 1883), wherein a young man of eighteen, falling from a height of thirty feet, and having his wrists doubled beneath him, received a perfectly symmetrical Colle's fracture of each wrist. The typical photograph accompanying the report, leaves no room for doubt as to the correctness of the diagnosis. Straight anterior and posterior splints, not reaching much beyond the wrists, and drawing the hands to the ulnar side, were applied.

Chromic Acid in Affections of the Mouth.

The *Med. Record*, Oct. 20, 1883, says: Dr. Cauquil, writing to the *Bulletin Général de Thérapeutique*, No. 12, vol. civ., concerning the employment of chromic acid, as recommended by Dr. Butlin in diseases of the tongue, states that he has also found it of value in stomatitis. He has used it with success in mercurial sore mouth, in the strength of one to five. In other cases of syphilitic pharyngitis with hypertrophy of the tonsils he has obtained good results with the same solution.

How to Destroy the Carcasses of Animals Dead of Contagious Diseases.

This question has been occupying the time of the French Academy of Sciences. The new process of M. Girard consists in dissolving the car-

casses in cold concentrated sulphuric acid, and utilizing the resulting liquid for the production of superphosphate of lime. At the end of eighty hours the entire carcass is dissolved in the acid, and only a colored liquid remains. The destruction of germs is thus complete, as has been proved by inoculation with the insoluble residue of the liquid. According to recent experiments made at St. Gobain, 321 kilogrammes of sulphuric acid (at 60° proof) dissolved in ten days nine sheep weighing 204 kilogrammes. From the 525 kilogrammes of liquid remaining, M. Girard extracted 25 kilogrammes of grease, and 500 kilogrammes of acid, which, mixed with 440 kilogrammes of coprolites from Ardennes, produced 940 kilogrammes of superphosphate of lime, containing 30 per cent. of nitrogen. In addition there was a quantity of soluble acid and insoluble phosphoric acid obtained.

The Treatment of Granulated Eyelids.

Jequirity is coming strongly into vogue in the treatment of granular conjunctivitis, and it seems to be a remedy that promises much. Dr. F. C. Hotz recently read a paper before the Chicago Medical Society (*Ass. Jour.*), which thus concludes:

1. Jequirity is the best known remedy for chronic granular conjunctivitis.

2. It is the most efficient remedy for clearing a trachomatous pannus, and in inveterate forms of pannus it is preferable to the operation of peritomy, as well as inoculation of blenorrhoeal virus, because it works quicker than the operation, and is safer than the inoculation.

3. It has no injurious effect upon the eyes, and can be used with perfect safety, even where the cornea is ulcerated.

4. It should not be used while the cornea and conjunctiva are actually inflamed.

5. It does not benefit those cases of chronic conjunctivitis in which the symptoms of catarrh (succulence of the retrotarsal folds with increased secretion, etc.), predominate over those of trachoma.

6, and lastly. The more violent the attack of the jequirity ophthalmia is, the quicker will be the cure of the granulated lids, and the speedier will the clearing of the cornea be produced.

Cauterization of the Lung.

We recently had occasion to note that this operation had been performed in Germany, and it now affords us pleasure to see that the *Med. Rec-*

ord, December 22, 1883, deprecates its performance. It wisely says:

"There certainly seems need of further experimentation upon animals before the human lung shall be considered a legitimate field for the exploits of the surgeon. And these experiments should be genuine efforts to relieve diseased conditions. Because a healthy dog will survive the removal of a part or the whole of one lung, it by no means follows that a like result is to be anticipated in the case of a man whose lungs are infiltrated with tubercles, and whose vital power is already greatly reduced. When it is found that an animal with tuberculosis can be cured, or even greatly benefited, by the canterization or exsection of the diseased pulmonary tissue, it will then be time enough to make cautious attempts in the same direction upon the lungs of the human subject."

Observations on the Normal Temperature of the Human Body.

Before the Liverpool Medical Institution (*Med. Press*, October 31, 1883), Dr. Carter read a paper based on a series of original observations made on the staff of night nurses in the Royal Southern Hospital. Two sets of observations were made at an interval of some years, and the results obtained in both were nearly identical. They showed—

1. That the normal temperature of the human body during the hours of night and early morning is lower than has been generally believed.

2. That the daily range of normal temperature is consequently greater than is usually accepted, amounting sometimes to three degrees Fah.

3. That this great periodic change is not affected by change of habit, but is as great in those who are well seasoned to night work as in those who are unaccustomed to it.

4. That it is but little affected by food.

Tannate of Sodium in Chronic Nephritis.

In *Centralb. f. Klinisch. Med.*, September 1, 1883, Lewin first recommended tannate of sodium in nephritis, and Ribbert's experimental researches demonstrated its action in causing decreased elimination of albumen.

Briese has used it, in four cases in Mosler's clinic, prepared as follows:

R. Solution of tannic acid, 2 parts to 100; add solution of bicarbonate of soda (9 to 5) ad react. alcalin. S.—Dose, one tablespoonful every half hour.

This mixture was not equally well taken by

the patients. In some cases it caused gastric disturbances and vomiting. The daily quantity of albumen eliminated by the urine was not diminished, the nephritis went on, and the patients grew worse daily; and it was apparent that the remedy was, in these cases at least, of no value whatever.

Therapeutic Use of the Magnet.

The *Alienist and Neurologist*, July, 1883, says:

Dr. D. L. Barraquer (*Gaceta Medico Catalana*), reports two cases in which marked relief followed the application of the magnet. The first case was cerebral hemorrhage with consecutive hemiplegia. The hemorrhage had occurred three years previously. One application was followed by visible improvement, and after four sances the forearm and finger could be fully extended. The second case was a boy suffering from deafness, due to middle-ear disease secondary to measles. Galvanism had been employed eight times, with the effect of increasing the hearing distance from 0 to 1 foot. The magnet was tried, and, after a half hour's sitting, the hearing distance was increased to three feet. At the fifth seance the watch could be distinctly heard at a distance of fifteen feet.

The Administration of Quinine.

In the *London Practitioner*, Dr. David Young enunciates the following:

1. Never to give quinine in antipyretic doses in cases where the bowels are confined and the secretion of urine is scanty.

2. In cases where it is being administered and an increase of dose is desirable, this may be safely done if the skin, bowels, and kidneys maintain their normal functional activity.

3. In many cases of remittent and intermittent fevers, the combination of the drug with chloride of ammonium or a salt of potash or soda is likely to be more easily tolerated, as well as more useful, than if it be administered in a pure form.

4. During the administration of quinine should a headache come on or increase in intensity, the case requires the most careful attention.

Phosphate of Codeia.

The *Boston M. and S. Jour.*, September 20, 1883, says: An English contemporary remarks that Herr E. Merck, of Darmstadt, at the instance of Professor Hegar, of Freiburg, has succeeded in producing a phosphate of codeia, which has the great merit of being soluble in four parts of water, so that it can be used subcutaneously. It crystal-

lizes in small four-sided columns, is white, rather bitter to the taste, and resembles the sulphates and hydrochlorates of the same base. In its action it resembles morphia, except that it is milder, and the symptoms of intoxication are less pronounced. The dose required is about double that of the salts of morphia. No marked local disturbances followed the subcutaneous employment of the drug.

Iodoform in Ophthalmic Therapeutics.

The *N. Y. Med. Jour.*, November 10, 1883, says that Vossius (*"Archiv. für Ophthalmologie, xxix., 1"*) recommends iodoform in all ulcerative processes of the cornea, especially in *ulcus serpens*. The earlier the case applies for treatment, the more rapid and favorable is the effect. Its use is not contra-indicated by any complication of the iris. He also advises its use as an antiseptic in all superficial and deep, accidental and artificial wounds of the conjunctiva and cornea, as well as in wounds of the sclera. He has but rarely noticed any evil effects from its use, and never any abscess of the conjunctiva; nor has he ever met with the amblyopia spoken of by Hirschberg, and attributed by the latter to the use of this drug.

Salicylic Acid as an Application to Epitheliomatous Growths.

The *Brit. Med. Jour.*, November 10, says that in an interesting case of rapidly growing epitheliomatous vegetations springing from the floor of a rodent ulcer, Mr. Thomas Smith advised Mr. Howard Marsh to use a saturated solution of salicylic acid as a local application. Mr. Smith said that, some time ago, he had been induced to make use of this remedy in the treatment of simple papillomata, and the result had been so favorable that he was led to apply it to epitheliomatous cases also. In the first case, which had now been under observation for some time, the application was entirely successful, the epitheliomatous growth having been entirely destroyed in two or three weeks.

Nervous Dyspepsia.

In persons of a nervous temperament, especially excitable women, we will frequently meet with a form of dyspepsia, not amenable to ordinary treatment. We recently had a case, in a woman, caused evidently by mental worry, in which there was great depression of spirits, a globus hystericus and a great oppression, with constant and violent eructations of wind, always greatly ag-

gravated by eating. Antacids, pepsin, and a host of routine remedies, were useless; she was then ordered tincture of valerian and bromide of potash in small doses (ten drops of the former and two grains of the latter) every hour. The dyspepsia and nervous irritability commenced to yield after the second dose, and soon disappeared.

Early Incision in Cervical Abscess.

It is becoming a gradually recognized rule that it is better to evacuate abscesses as early as possible rather than to wait, as heretofore, until they are nearly ready to burst. The argument is that nothing is to be gained by delay, while serious results may ensue from the burrowing of pus and other causes. More especially is this early operative interference recommended for cervical abscesses, on account of the vital nature of the elements of this region. To the other cases reported, Dr. F. R. Campbell adds an instructive one in the *Buffalo Med. and Surg. Jour.*, Dec., 1883, where, although no fluctuation could be detected, yet the bistoury was used, and when subsequently poulticing encouraged a free flow of pus, a probe demonstrated that the pus had so burrowed that a fatal internal rupture would have been much more likely than a natural external opening.

The Micrococci of Acute Osteo-mylitis.

Dr. Koch has found micrococci in the pus obtained from osteo-mylitic abscesses, and he publishes his experiments with them in a recent issue of the *Deutsch. Med. Woch.* After cultivating them on boiled potato, he inoculated various animals, but failed to produce osteo-mylitis. When, however, a bone was crushed or fractured a few days before the inoculation, the disease was developed by them, which points to the rather instructive fact that, in order to produce osteo-mylitis of this acute infective type, not only must there be a specific virus in the system, but there must also be a local inflammatory process, or, if it be preferred, a local injury to the tissue, which becomes the seat of infective inflammation in the presence of the prime factor—the virus in the blood.

Dystocia Due to a Vaginal Cicatrix.

Cicatricial bands stretching across the vagina and so interfering with the progress of labor, are sufficiently rare to make the case reported by Dr. M. Wallace in the *Canadian Practitioner*, December 1883, interesting. From the anterior to the posterior walls of the vagina stretched strong bands,

the results probably of vaginal lacerations in previous difficult labors, and when the head descended it was arrested by them. The finger-nail was used to scratch through the band that was most stretched. Forceps were applied, and after an hour's hard pulling, one of the bands gave way with a perceptible noise, and the child was delivered. On the eleventh day she died with symptoms of internal hemorrhage, but a post-mortem was not obtainable.

Santonin for Gleet.

Dr. Wm. Anderson thus writes to the *Lancet*, November 10:

"In treating a patient some months ago for lumbrici, he said to me, 'You have not only killed the worms, but you have cured my gleet.' I may mention that the gleet had been obstinate, of long standing, and recurrent in spite of the usual remedies. He has had no return since. In 1864 I published a paper on santonine, but although I then made some experiments showing its effects upon the urine, it never occurred to me to try it in gleet or gonorrhœa. The formula I recommend is: Santonin, sacchari lactis, ãã gr. v.; terebene et ft. pulv. To be taken twice a day, fasting, in milk."

Bromide of Arsenic in Diabetes.

From the *Jour. de Med. de Paris*, October 13, 1883, we learn that Dr. Pekai, of Buda-Pesth, has been much gratified with the success of this treatment. He began by putting three drops of the medicine in one ounce of water, and this was taken in three doses; this was increased by one drop every three days, until ten drops were taken daily. The solution is prepared as follows: Grs. iss ãã of arsenious acid and carbonate of potash are placed in a brine measurer (éprouvette); gtt. v of water are added, and treated until the liquid is limpid. Then add sufficient water to make ten grammes (3i iss by weight). Add, then, grs. iss of bromine, and leave for twenty-four hours.

Syphilitic Cephalalgia.

We recently had a case of acute pain radiating over the vault of the cranium in a woman whom we knew had been infected about 18 months previously. From the woman's exalted moral standard, no one would have suspected a syphilitic taint. It was innocently contracted in a charitable ministration. This we know. Dry cups, blisters, and all the usual anti-neuralgic treatment, had no more effect than so much water.

Finally, large doses of the iodide of potassium (10 grs. every four hours) and biniodide of mercury ($\frac{1}{16}$ gr.) were given, and like magic, the intense pain, that had lasted for two weeks, disappeared. An extensive iodide eruption appeared all over the body.

Chloroform Locally to Relieve Pain.

When applied to the skin as vapor, chloroform is much less irritating than when used as a liquid. Dr. Huesner (*Deutsch. Med. Woch.*, October 30, 1883,) uses shallow tin cups, so curved that they may be closely applied to the desired part. In the cup he puts a piece of lint, saturated with a few drops of chloroform. To make the cup fit tight, a rubber band is put around its edge, and it is fastened on with a rubber band. A simple wineglass will answer. He has had good results in pleurodynia, dry pleurisy, headache, and earache. It is not of much use in deep-seated pain.

Purpura from Quinine.

The indiscriminate use of quinine can do more than produce the ordinary cerebral symptoms of cinchonism, for Dr. E. Wigglesworth tells us (*Boston M. and S. Jour.*, December 20, 1883,) of a woman who noticed a scarlet, non-elevated, irregularly circular patch, about as large as a silver half dollar, on her forearm, one hour after taking one grain of quinine; she took eleven more grains, and the spots increased in number. Upon discontinuing the quinine, the spots desquamated and disappeared.

Tardy Action of Pilocarpin.

Dr. F. W. Ellis, of New Richmond, Wis., writes to the *Med. Record*, October 6, 1883, that on January 10 he gave a boy, aged three years, suffering from ascites, a course of pilocarpin, covering two days. From the 11th to the 16th there was no effect. On the night of the 16th a fly-blister was applied. On the 17th all the characteristic symptoms of jaborandi appeared; profuse sweating and salivation, so that the circumference of the abdomen diminished two inches.

Injections of Ether for Sebaceous Cysts.

Make the tumor tense by pressure and inject by a Pravaz syringe 5-10 drops of ether into the largest aperture noticed. Repeat every second day, until inflammation is set up. Then puncture the base of the tumor, when pus will escape, followed by broken-down sebaceous matter, and the

tumor is cured. This is the treatment recommended by M. Vidal in *Bull. Gen. de Therap.*, November 30, 1883.

A New Use for Apomorphia.

This valuable emetic has proved serviceable in two cases of hystero-epilepsy reported by Dr. T. Hammond Williams in the *Med. Times and Gaz.*, December 8, 1883. In the one case the attacks were probably due to suppression of menses, in the other their etiology was obscure. In both, however, they diminished in intensity and ultimately disappeared under the hypodermic use of apomorphia in doses of one-fifteenth of a grain.

Cerebral Syphilis.

Apropos of our editorial on this subject (see page 21) the case reported in the *Boston M. and S. Jour.* December 20, 1883, by Dr. Egbert H. Grandin, is worthy of note. The patient was a lady aged 35, who had been syphilized by her husband fourteen years previously. Last summer she was suddenly seized with a paralytic stroke, and though she improved for a time under large doses of iodide of potassium and mercurial ointment (for syphilides), she had a convulsion, and passing into a comatose state, died early in November.

CORRESPONDENCE.

FOREIGN CORRESPONDENCE OF THE REPORTER.

Prof. Von Bergmann in Office and Operating Room.

EDS. MED. AND SURG. REPORTER:—

Prof. Von Bergmann, who succeeded Prof. Langenbeck in the surgical department of the University of Berlin about a year ago, has more than maintained the prominent position which the chair occupied under his predecessor. Arriving in the city shortly before the beginning of the winter semester, and consequently of public operations in the operating amphitheatre, through the courtesy of an acquaintance I waited on Prof. von Bergmann to request permission to attend a private operation in the hospital.

A physician's office here on the ground floor would be a novelty. A room, or suite of rooms, as every traveler well knows, is commonly rented up one or two long flights of stairs in some one of the vast buildings, which are cut up into flats, offices, and stores, and of which the city is largely composed. The comfortable, individual dwellings so common with us for the middle and upper classes, and which have come to be synonymous with "home" in our eyes and hearts, are depressingly absent. The great surgeon is no exception to the rule. I found his quarters in a

large flat facing the shipping and narrow quays of the Spree. A ring at the portier's bell and the door mysteriously springs ajar, but no one appears. Instinctively you climb the long stairs, broken by landings. Another door, and the physician's name on a small tablet beside it. Another bell, and a maid-servant appears, and you follow through a narrow, dark corridor, and are ushered into a large room, dimly lighted. It is the single hour allotted for office consultations late in the day, and a number of persons are waiting. By the aid of the gaslight, you discover the room is furnished much like a parlor, and that magazines and periodicals are lying on the centre-table. Some love-birds are engaged in their endless amours, and a tank of goldfish are quenching their eternal thirst.

Presently the professor appears. He is without assistant, and disposes of his cases rapidly as they enter his private room. He is a middle-aged man, with a large nose and long hair, large, dark, alert, brusque, uneasy mannered, and restless. In a hurried monotone, he makes an appointment for the following morning, and is speedily busied with the next comer.

* * * * *

Prof. von Bergmann belongs to the school of believers in thorough antiseptis. The operation about to be performed was for resection of the right hip-joint in a man about forty-five years of age. The operating room was a small, well-lighted one, with painted walls, in one of the buildings of the Royal Clinic. His assistants were Drs. Zeller and Glück. After the administration of chloroform, an incision was made over the trochanter major, longitudinally with the *gluteus maximus*. A quantity of pus, containing muscular debris, escaped as soon as the cavity around the joint was penetrated. The bone was denuded of periosteum and twice amputated with a chain-saw. The head of the femur had been destroyed, and the extremity of the shaft slightly invaded. The walls of the cavity were carefully scraped and antiseptically cleaned, and the acetabulum partly chipped away with a chisel. A pus cavity on the inner side of the thigh was likewise evacuated by a free incision. No blood-vessel of any size was wounded. Both cavities were thoroughly washed and syringed out with a solution of iodoform (10%) in ether, and afterwards dressed by covering the surface with several grammes of powdered iodoform and filling the incisions with pieces of very thin, open meshed cotton-cloth, which had been cut in strips and saturated with a solution of corrosive sublimate, 1 to 1,000. This cloth, which is prepared by a somewhat complicated process beforehand, was also piled over the cavities, and then the limb and lower part of the body enveloped in repeated layers of it, between which was first spread oiled silk, and afterwards two long strips of felt (2x½ inches) reaching from the waist to the foot. After a week or ten days, extension will be kept up with a weight of from eighteen to twenty-five pounds. After several weeks, the dressings will be removed.

NOTES.

The most scrupulous attention is paid to cleanliness in the hands and finger-nails of the operator

and assistants. After a thorough washing, the hands are dipped in a solution of corrosive sublimate, 1 to 1,000. This was repeated several times during the operation, and the person of the patient around the point of incision was also similarly washed and treated.

Before and during the operation a spray of carbolic acid solution, 3 to 100, continuously played on the part operated on, covering surgeons and nurses, as well as patients, with a fine drizzle.

All operating instruments and ligatures are kept in an antiseptic solution during the operation, except when in use; the instruments lying in the carbolized preparation. The sublimate solution is Prof. von Bergmann's favorite antiseptic, when practicable. He first introduced it six years ago at Würzburg.

The operating-table is covered with a heavy sheet of rubber, one-half inch thick, which is easily and thoroughly cleaned and kept free from septic infection. Chloroform only is used. It is administered by means of a piece of flannel cloth stretched over a wire cone, about the size and shape of a very small bowl. Patients are not allowed to eat on the day of the operation, before its performance. Nausea is comparatively rare, and deaths on the operating-table very rarely heard of. The head of the patient rests on a cylindrical air cushion, which offers suggestions of convenience and cleanliness. The surgeon applied the bandages wholly himself. Everything was immaculately clean.

The iodoform, which to an American seems used with such astonishing freedom, not infrequently—according to Berlin physicians—produces delirium, and is even charged with more serious results. Dr. Fehleisen, one of Prof. von Bergmann's assistants, is continuing his experiments with the bacilli of erysipelas and inoculation with the cultivated poison, notice of which was taken editorially in the *REPORTER* several months since.

Berlin.

W. O. S.

Puerperal Eclampsia.

EDS. MED. AND SURG. REPORTER:—

On December 7, I was called to see Mrs. W—, primipara, aged 26, who was reported to be in convulsions. I had examined her urine the day before and found it very albuminous. As I reached her, she was having her fourth convulsion. As soon as she could swallow, I administered heroic doses of tincture of belladonna, with bromide of potash and sulphate of morphia. The fifth convulsion was delayed. She was then given by enema 100 grains of bromide of potash, which effectually controlled all convulsive movements. The consulting physician, Dr. Colburg, of Syracuse, who arrived about two hours after the last convulsion, recommended fluid extract of gelsemium in lieu of the belladonna; this was given, and also thirty-drop doses of fluid extract of jaborandi until free diaphoresis was produced. She was also given a large dose of salts, which purged her freely. She was then put upon digitalis, (five drops) and sweet spirits of nitre (half a drachm) every five hours. She did not regain consciousness until the morning of the 9th. At two a. m. on the 10th, labor began and was completed with-

out an untoward symptom. The child was still-born.

S. R. MILLER, M. D.

Dunbar, Nebraska.

Letter from Dr. S. Weir Mitchell.

EDS. MED. AND SURG. REPORTER:—

Will you kindly publish the following statement, made necessary because of my receiving letters from England and this country calling my attention to the liberty taken with my name?

Dr. H. H. Kane, of New York, has made use of my name in an advertisement of a secret means of treating the opium habit; and afterwards, in a pamphlet labeled "De Quincey Opium Home Cure," printed fac-similes of letters received by him years ago from a number of physicians, and among them a letter of mine. In obedience to a protest on my part, Dr. Kane has removed my name from his advertisement, and my letter from his pamphlet.

Yours truly,

S. WEIR MITCHELL, M. D.

December 22, 1883.

A Formula for Koumiss.

EDS. MED. AND SURG. REPORTER:—

I enclose you a formula for koumiss as follows, for family use: Take of milk one quart, $\frac{1}{4}$ of a teaspoonful bicarb. soda, $\frac{1}{2}$ of a cake of compressed yeast, two tablespoonfuls white sugar, three tablespoonfuls glycerine. Rub the yeast up smoothly with a small portion of the milk, and mix all together in a quart bottle, cork tightly, and keep in a temperature from 80° to 100° Fahr. for six hours, then in ice-box for twelve hours, and use.

This is the easiest method I have tried, and I think will suit very well for domestic purposes, but it differs from most formulæ published.

J. F. HAYES, Druggist.

Broad and Walnut sts., Phila.

NEWS AND MISCELLANY.

American Medical Literature.

In the course of an address entitled "The Place of Literature in Medicine," Dr. C. J. Cullingworth (*Lancet*, December 8, 1883,) says:

"One of the best medical monographs with which I am acquainted is on 'Diaphragmatic Hernia.' Its author is Dr. Bowditch, of Boston, U. S. A., and it is founded on an analysis of eighty-eight cases. In this little book, scarcely larger than a pamphlet, is brought together all that, by the most patient search, could be found relating to the subject 'in medical literature during the period 1610 to 1846.' Such work soon becomes intensely interesting, as I can testify from my own experience, and that Dr. Bowditch found it so appears evident from the concluding sentence of his preface, in which, after expressing the hope that the memoir will be useful to the future student, he declares that 'the examination of it can never afford any one a tithe of the pleasure or profit the original preparation of it afforded' to himself.

"I hold in my hand another typical example of a medical monograph, the subject of which is the 'History and Treatment of Placenta Previa,' and the author, again an American, Dr. William Read, of Philadelphia. It is larger than that of Dr. Bowditch, because it has reference to a less uncommon affection; but its execution is equally admirable. I should have liked to give you an idea of the plan pursued by each of these writers, as shown by the mode in which they divided their inquiries, and the special points elucidated in each chapter."

It is a pleasure to record English appreciation of our efforts, and it will, no doubt, serve to stimulate us to accomplish even more than we have done.

Professional Rewards.

The *Gazette Hebdomadaire des Sciences Medicales de Montpellier*, for June 30, 1883, tells us that Dr. Monnet last January, while passing through a certain street, went to the assistance of a drunken man whom he saw fall and injure his head. He had him taken to an apothecary's shop, gave him a medicinal mixture, and dressed his head, for which he received a severe blow with the fist. Ten minutes later the drunken fellow was walked out of the shop by a policeman. As the doctor was about to follow, the apothecary demanded 36 cents of him as the price of the mixture, which the doctor refused to pay. A few days later Dr. Monnet received two letters; one from the apothecary, summoning him before a justice of the peace; the other from the police authorities, requesting him to appear and give information regarding the drunken man. The doctor, being a very busy man, neglected to pay proper attention to these letters. Consequently in March last an officer presented himself with the intention of attaching the property of Dr. Monnet, and he found that by this time he had to pay for the sake of the law the sum of \$9.96.

The Effects of Opium Smoking.

From the *Med. Times and Gaz.*, December 8, 1883, we learn that Dr. Ayres, the British Colonial Surgeon at Hong Kong, in his report on the prisons in that colony for the year 1882, says that among the prisoners in the gaol who are set down as opium-smokers there have been no deaths, and he has not found among them any cases of disease which could be attributed to this habit. The heaviest smoker, a man who consumed in this way fifteen grains of opium a day, and had been a smoker for thirty years, weighed 107 pounds on entering the gaol, and in three weeks he gained 3 pounds, although he underwent penal diet, that is to say, for five days out of fifteen he had to subsist on rice and water only. Dr. Ayres declares the opium-smoker suffers much less from the enforced deprivation of the accustomed luxury at once than the tobacco-smoker, and there was no particular symptom caused by the deprivation. Many make no complaint at all.

Lack of Anatomical Facilities in Vienna.

The Vienna correspondent of the *N. Y. Med. Jour.* says that dissecting privileges in Vienna are

not all that they have been represented to be. Aside from the fact that the subjects are never injected with preservative fluid, and hence will keep but a short time, there is a curious, unscientific custom which prevails here, of lopping off a number of limbs, and dealing them out separately for dissection. Add to this the difficulty and annoyance which a foreigner experiences in trying to obtain fresh material, and the necessity of renting a private room in which to work (for the Vienna medical student has very crude ideas regarding the rights of his co-laborers); and it remains a matter of considerable doubt whether it pays for a graduate to spend much of his time here in practical anatomy. He may gain in quantity, but with a proportionate loss in quality.

A Fine Wine.

For a sound, generous, rich wine, combining the highest therapeutic effects with the minimum of reaction, we have found nothing superior to the Hungarian "Tokayer Ansbruch" imported and sold by Mr. L. Reich, 13 West Eleventh street, New York city. In cases of nervous exhaustion, debility from acute disease, impairment of energy from overtaking the powers, and to retard the gradual failure of the constitution from advancing life, we have seen ample evidence of its excellent results. It vindicates for wine the lofty position which it used to occupy in the *materia medica*, but from which it has fallen through the introduction of so many base articles under that name. Those who desire Mr. Reich's wines should write him directly, as he does not sell any of them through drug houses or the trade.

Coated Tongues.

The *Microscope* gives the following as some of the articles found by microscopical examination on coated tongues. Fibers of wood, linen, and cotton; fibers of spiral vessels; fibers of muscle, in one case eight hours after eating; starch grains; cheese mold; portions of potato skin; scales, moths, etc.; hairs from legs of bees; hairs from legs of spiders; pollen of various flowers; stamens of various flowers; hairs of cats, quite common; hairs of mouse, once only; hairs from various leaves; wing of mosquito, once; fragments of the leaves of tobacco, chamomile flowers, etc. A list ten times as long could be made, but *jam satis*.

The Boston Public Schools.

It has been decided that the reports recently made by the Sanitary Inspectors in regard to the condition of the public schools are to be carefully examined by a joint committee from the Board of Health and Board of Education, and needed changes are to be made in those buildings which demand immediate attention. It would be well for the future generations if the sanitary authorities of all cities should be consulted in reference to the public school buildings.

Typhoid Fever in New Haven.

The city of New Haven is having at the present time an epidemic of typhoid fever similar to

that of Providence in 1882. No definite, single cause can be assigned for the outbreak, and the *Providence Daily Journal* very wisely says:

"In New Haven, as in Providence, careful investigation finds sufficient local causes for the fever in more than seventy-five per cent. of the cases that exist. In New Haven, as in Providence, typhoid fever is a filth disease, and people, whether they live in palaces or in hovels, do not have the disease unless they breathe foul air or drink impure water."

Diphtheria from Defective Sewerage.

The investigation of the recent outbreak of diphtheria in the Blind Asylum at Batavia (N. Y.), by the State Board of Health, showed that the interior sanitary arrangements of the building were very defective, and that the large drain which conducted the sewage to a swamp back of the institution, and which was of concrete, had fallen to pieces, while the earth had caved in and blocked up the passage. The asylum will remain closed until the improvements now in progress under the direction of the Board have been completed.

An Outrageous Suit for Manslaughter.

A physician in London recently performed tracheotomy upon a child for diphtheria; the father sucked the tube to clear it, and contracted the disease. He then brought suit against the doctor for damages, claiming that the doctor ought to have sucked the tube himself. Failing in this suit, he instituted another for manslaughter, because the doctor did not cure his child. Such instances are enough to frighten a man out of the profession. Happily they are rare in this country.

OBITUARY NOTICES.

DR. THOMAS KIRKBRIDE.

Dr. Thomas Kirkbride, the veteran Physician-in-chief and Superintendent of the Pennsylvania Hospital for the Insane, died in this city, December 17, aged 75 years. His illness dates from an attack of pneumonia last March, though he really died from the natural exhaustion of vital power incident to his advanced age.

Dr. Kirkbride was born near Morrisville, Bucks county, July 31, 1809. His ancestors on both sides were, as he was himself, members of the Society of Friends, and were among the first settlers in Pennsylvania, and the associates and companions of William Penn. He received an academic education at Trenton and Burlington, N. J., and in the spring of 1828 studied medicine under Dr. Belleville, of the former place, and subsequently attended three full courses of lectures in the University of Pennsylvania, whence he graduated in March, 1832. In the following month he was appointed Resident Physician to the Friends' Asylum for the Insane, Frankford, in which position he served a year, and in March, 1833, he was elected Resident Physician at the Pennsylvania Hospital, where he remained two years, after which he engaged in private practice in this city, devoting himself principally to sur-

gery, which practice he pursued until December, 1840. During this period he was physician to various public institutions, among them the House of Refuge, Institution for the Blind, and Magdalen Asylum. In the fall of 1840 he was elected Physician-in-chief and Superintendent of the Pennsylvania Hospital for the Insane, a new establishment then recently completed, and to which it was proposed to remove the insane from the Pennsylvania Hospital, at Eighth and Pine streets. The new hospital was opened January 1, 1841, when he removed his family to the institution, and has since resided there, acceptably filling the position to which he was elected 42 years ago. During Dr. Kirkbride's administration the number of patients treated has increased from hundreds to thousands, and he has been instrumental in securing many decided reforms in the care and treatment of these afflicted patients. In 1854, the original building having become crowded, he recommended the erection of a new one on the grounds of the institution, and a complete separation of the sexes. He further recommended that the proposed building should be erected through an appeal to the public, which was accordingly made, and with entire success, the building being completed wholly from private contributions, exceeding in the aggregate \$355,000. The second building, which is now appropriated to males, was opened October 27, 1859.

Dr. Kirkbride has written a work on the "Construction, Organization and General Arrangement of Hospitals for the Insane," "Rules and Regulations for Hospitals for the Insane," and "Rules for the Government of those Employed in the Care of the Insane," besides contributing various articles and reviews to the *American Journal of the Medical Sciences*, the *American Journal of Insanity*, and other periodicals. He was one of the original founders of the Association of Medical Superintendents of American Institutions for the Insane, of which he was President for nine years, a manager of the Institution for the Blind from near the time of its first foundation, and present Vice President, a member of numerous medical and scientific associations, including the American Philosophical Society, Philadelphia College of Physicians, and the British Psychological Association, of which he was an honorary member. He has a son, Dr. Joseph L. Kirkbride, engaged in private practice in this city, and a daughter, the wife of Dr. Thomas G. Morton, the eminent surgeon. About fifteen years ago he married his second wife, Miss Butler, a sister of William Allen Butler, of New York, and who, with four children, survives him.

Dr. Kirkbride combined with his great mental abilities the rather unusual attribute among great men, of simplicity and purity of personal character. He was a truly great man, great in his objects and great in his accomplishments, and we feel that his death will leave a great void in the ranks to which he belonged.

Items.

—Dr. Philip Leidy recommends oil of citronella (two drops to the drachm) to disguise the odor of iodoform.

—Color-blindness in the navy is probably to be made the subject of an investigation by order of Congress.

—The Russian physician, Dr. Eck, sent to Egypt to investigate the cholera, says that it was undoubtedly imported from India.

—The *Pittsburgh Medical Journal* has temporarily suspended publication, owing to the prolonged absence in Europe of its editor.

—A medico-legal society has been organized in Philadelphia. Professor John J. Reese delivered an address before it at its opening session.

—Dr. J. Marion Sims is said to have left ready for publication a story of Revolutionary times, entitled "Lydia McKay and Colonel Tarleton."

—The German Cholera Mission has gone to Calcutta, instead of Bombay, as at first intended. Better facilities are to be found at the former place.

—In the *Med. Times and Gaz.*, December 8, 1883, Mr. Rickman Godlee reports a case of erysipelas following the use of chrysophanic acid for ringworm.

—An apparently well-marked case of Raynaud's disease is recorded in the *Gazette Médicale de Paris* for December 1st. There was glycosuria, but no mention is made of hemo-globinuria.

—An English physician states that he has known one of his prescriptions to be made up without his order to his patient more than three hundred times. He was paid for only one prescription.

—In a village called Strichen, near Aberdeen, Scotland, there was recently an epidemic of typhoid fever. The source of the infection has been traced to a farm which supplied the milk, and where there were cases of typhoid fever.

—The existence of a micrococcus of pneumonia has been confirmed by Professor Carl Friedländer, of Berlin, who has cultivated these organisms and produced croupous pneumonia by inoculating them in dogs and mice.

—The New York State Board of Health reports as a result of its investigation into the cause of malaria along the Hudson, that this disease has been brought about, in part at least, by the railroads making embankments which prevent free drainage into the river.

—The water supply of the city of Waterbury, Conn., drawn from Mad River, is reported to have become quite impure of late, owing, it is supposed, to the river having been tainted with refuse material from a number of factories that have been established on its banks.

—A communication to the Académie des Sciences, made by MM. Chambrelent and Moussons, has for its object the demonstration of the passage of the bacilli of charbon from the blood into the secretion of milk. The number of bacilli in the milk of affected animals is always much smaller than that in the blood, and may even be reduced to zero.

QUERIES AND REPLIES.

W. E. Moore, Derby, Ia.—Your query in relation to koumiss is answered in this week's journal.

MEDICAL SYMBOLISM.

BY T. S. SOZINSKEY, M. D.,
Of Philadelphia.

(Continued from page 5.)

One can advance sufficient evidence to indicate with considerable conclusiveness that the Egyptians were in the habit of looking to a serpentine divinity for the cure of disease. In his work, already quoted from, Sharpe gives a figure of a snake, wearing the crown of Upper and Lower Egypt,* on a pole, a cut of which is reproduced

here: (Fig. 5), which was carried in the periodical airing procession of the Egyptian divinities. Now, it is more than probable that Moses was very familiar with this figure and its import; but at any rate, we find him making an imitation of it, and for what purpose? The story is told in the Bible,† and runs thus: "And Moses made a serpent of brass and put it upon a pole; and it came to pass that if a serpent had bitten any man, when he beheld the serpent of brass he lived."‡ Verily, there is the healer in essentially the same form in which he was embodied by the Romans. Hence, it is very certain that the serpent as a symbol of medicine took shape before the time of Æsculapius, long before, for

FIG. 5. Moses lived nearly 400 years earlier

than he, and as we have just seen, it was likely far from new at his time.

But the association of the serpent with Æsculapius, as a remnant of a form of serpent-worship, may have come as a direct inheritance, like the laurel, from Apollo, the sun-god, with whom, as we know, one was, almost everywhere, sacred. Mr. C. F. Keary maintains, in his able work,* that the tree, mountain and river were the three great primitive fetich-gods of the early world, and forcibly argues that a serpent was the symbol of the last, which, it may be noted, is nearly always a life-giving power. Without pretending to account for their original worship, he "takes it for certain that at a very early time rivers became through symbolism confounded with serpents." Remnants of these fetichisms are preserved in later and more abstract cults, and may be largely found in Indo-European mythologies. The monstrous python which Apollo encountered and destroyed at Delphi was simply a river, and a harmful one, ulteriorly a river of death. The Fardarter, through his arrows (rays), dried up the water. "The reptile was, we know," says Mr. Keary, "before all things sacred to Æsculapius, and was kept in his house, as for example in the great temple of Epidaurus. It would seem that the sun-god has the special mission of overcoming and absorbing into himself this form of fetich. This is why Apollo slays the python, and why the snake is sacred to Æsculapius." Between tree- and serpent-worship the connection is close, as

said of Hezekiah (2 Kings xviii. 4) that "he removed the high places and brake the images and cut down the groves, and brake in pieces the brazen serpent that Moses made; for unto those days the children of Israel did burn incense to it: and he called it Nehushtan."

* Outlines of Primitive Belief.

* Vide description in Exodus xxviii. and xxix.

† Numbers xxi. 9.

‡ This idol was not appreciated only for a time, for it is

one would expect from the close connection in nature between rivers and trees.

It is proper to state, although I must be brief, that there are other ways of explaining serpent-worship besides that so ably advocated by Mr. Keary. It is suggested by Fergusson* that the longevity of the reptile may be one reason for it, and its mysterious and deadly power another. One of the most tenable theories is the phallic, † and another which is held by many is the astronomical. Says Lillie, ‡ “Like all old religious ideas, the serpent symbol was probably in the first instance astronomical. Two thousand eight hundred and thirty-six years before Christ, a large star was within one degree of the celestial pole. This was the *a of Draco*.” Much interest was taken in it, as readers of the works of Messrs. Piazza Smyth and Proctor are aware. The constellation of Draco, or Dragon, was represented in ancient astronomy by a serpent twined round a tree, the prototype of which likely was the *Asclepias acidi*, the source of soma, the original intoxicant of the Aryans. With Draco, the Supreme Being and paradise were associated. Two snakes on a staff, an emblem very similar to the caduceus of Hermes or Mercury (the wind god), constitute the *Tria Ratna* of Buddhism, “the three precious symbols of the faith.” “These very ancient symbols,” says Lillie, “are Buddhist symbols, but they plainly indicate also the inner teaching of Vedism, the father and mother and the solar ‘golden germ.’” The symbol of Draca may be the prototype of Serapis, the serpent-encircled Egyptian god, as well as the staff and climbing serpent of *Æsculapius*. I may add that Plutarch || holds that the serpent-symbol of the supreme god, *Uraeus*, was the cobra di capello (*naja tripudians*), the rather venomous viper still worshipped in India.

As several medical symbols cannot be understood without a knowledge of the history of the half-mythical *Æsculapius*, I will explain those calling for special notice in connection with a sort of sketch of the god. An extremely remarkable history it is, and certainly of much interest to all medical readers.

As was a rather common event in the days of yore, if ancient writers are to be believed, *Æsculapius* was the offspring of an attractive young virgin named *Coronis*, a native of Thessaly, by one of the immortal gods, the gallant Apollo

himself, who, as I have stated above, was, in connection with his other functions, the Grecian god of medicine until his healing and life-giving powers were exercised by his son.* We learn from Homer, † that during the progress of the Trojan war, medical service was not infrequently invoked from Apollo (*Pæon*). Thus he was called on when the Lycian chief, *Sarpedon*, was wounded—

“Apollo heard; and suppliant as he stood,
His heavenly hand restrained the flux of blood;
He drew the dolours from the wounded part,
And breathed a spirit in his rising heart.”

The famous Hippocratic oath, which was taken by the medical student at his entrance on the study, begins with these words; ‡ “I swear by Apollo, the physician, by *Æsculapius*, by his daughters, *Hygeia* and *Pomaria*, and all the gods and goddesses.” Bacon ventures to say || that it was well for the poets “to conjoin music and medicine in Apollo, because the office of medicine is but to tune this curious harp of man’s body and reduce it to harmony.”

The laurel crown given to *Æsculapius* has been held by some to have been accorded to him, because he was the son of Apollo, the laurel being specially consecrated to the latter. Another way of accounting for it, is as stated by Tooke, § “because that tree is powerful in curing many diseases.”

The name of the mother of *Æsculapius*, *Coronis*, in Greek signifies crow. This is given as the reason why the crow was consecrated to the god. Another reason is because that watchful bird brought the unpleasant news to Apollo that the sly *Coronis* was secretly keeping company with a youth of her neighborhood (*Ischys*)—a piece of service which was unkindly rewarded by changing the tale-bearer from white to black, put permanently in mourning for the unfaithful maid.

In this connection I may remark that Thessaly, a region in which poisonous herbs abounded, was regarded by some, as, for example, Strabo, as the place of nativity of *Æsculapius*, as well as his mother. Referring to this, Blackie ¶ says: “That the knowledge of medicine came to the Greeks originally from Thessaly, one of the earliest seats

* A writer in Smith’s “Dictionary of Grecian and Roman Antiquities” remarks that the personification of the healing powers of nature is “naturally enough described as the son (the effects) of *Helios*—*Apollo*—or the sun.”

† *Iliad* and *Odyssey*.

‡ Buddha and Early Buddhism.

|| Isis and Osiris.

of Hellenic civilization, is evident from the pedigree of Coronis." However this may be, it is interesting to observe that there is testimony in Homer going to show that Egyptian medicine was in repute during the Homeric age. Thus, to remove the grief and rage caused by the death of brave Antilochus, we are told* that the famous Helen (a Spartan), who takes, on the occasion, the role of a "woman doctor,"

"Mix'd a mirth-inspiring bowl,
Temper'd with drugs of sovereign use t' assuage
The boiling bosom of tumultuous rage.

* * * * *

These drugs, so friendly to the joys of life,
Bright Helen learn'd from Thone's imperial wife,
Who sway'd the sceptre, where prolific Nile
With various simples clothes the fatten'd soil.†

It was the luck of Æsculapius to be an orphan from his birth, if birth he had, to speak correctly. When Apollo found that the conduct of Coronis was bad, he became very angry, as was to be expected, and ordered Diana to destroy her through a stroke of lightning, which was done. But he thought it well to save the child; and to do this, it is to be presumed, the operation now known as the Cæsarian was hastily performed. The operation was successful, but what to do with baby Æsculapius, who, it is not unlikely, was brought into the world prematurely, was puzzling to Apollo. It appears that the little unfortunate would likely have perished had it not been for the friendly offices of a goat and a dog. The goat gave the precious *enfant trouvé* nourishment, while the faithful dog guarded him from harm. Hence it is, we are told, that these animals came to be associated with him, the former in sacrifice. The dog has been given the credit of nourishing him, and the frequent association of the goat with him afterwards is explained otherwise than as stated above, namely, because, to use the words of Tooke,‡ "A goat is always in a fever; and, therefore, a goat's constitution is very contrary to health."

In progress of time, Apollo took care that Æsculapius should not grow up in ignorance; so the boy was put under a master, and a strange one, too, Chiron, who was very monstrously formed, his figure from the waist down being the body of a horse. This strangely-formed individual, a centaur, directed the attention of his pupil to the study of the medicinal virtues of plants; for he was a great herbalist, being called by Homer, in

the words of Pope, "the Sire of Pharmacy." A symbol in the form of this Thessalian monster is of pharmaceutical significance.

I am not particularly called on to speak further of Æsculapius personally, but I deem it desirable to say a few words about his medical career and other points, so as to make the sketch complete. His knowledge of drugs became greater than that of his master, Chiron, and his practical skill as a physician touched on the supernatural. His patients did not die, and a few he recalled from "the shades below." Of his plans of cure, Pindar,* after speaking of the sick that flocked to him, says:

"Some spells brought back to life;
These drank the potion bland; for these he bound
With drugs the aching wound;
Some leaped to strength beneath the helpful knife."

His great success in curing the sick, and especially his recalling some from the other world, led to his destruction. Pluto, the God of the infernal regions, not wishing a sparse population, became displeased with him and complained to Jupiter, who, likely believing that he was becoming too powerful, cut short his career through a thunder-bolt.

In the celebrated ode quoted from above, Pindar declares that the efforts of Æsculapius to recall the dead to life were inspired by temptation with gold; he says:

"Alas! that filthy gain can blind the wise!
The glittering gold betrayed the noble leech."

Making this ugly charge is probably unjust to the great physician. The historian Grote,‡ thinks so, and expresses the idea that Pindar was disposed "to extenuate the cruelty of Zeus by imputing guilty and sordid views to Æsculapius."

In the references of Homer to Æsculapius, he appears as simply a mortal, a fact which Blackie characterizes as remarkable; but after his death an Æsculapian cultus spread rapidly. As Cox says,‡ "there were few divine personages more widely honored than this son of Apollo." Temples called Æsclepiea were erected to him, to which patients flocked to be healed. At these resorts, one or more nights were passed, during which rules laid down by the priests were observed. The cure was usually suggested by a dream. The medical attendants or priests, in the Æsclepiea, were called Æsclepiades. Through the votive tablets, some of which are yet extant, which told more or less of the treatment, a considerable deal

* Odyssey, b. iv.

† Vide also note on Phæon below.

* Third Pythian Ode.

‡ History of Greece.

‡ Comparative Mythology and Folklore.

of medical knowledge was accumulated in these institutions. In the introductory remarks to his excellent edition of the works of Hippocrates, Adams says: "When we come to an analysis of the different Hippocratic treatises, it will be seen that there is strong reason to believe we are still in possession of two documents composed from the result of observations made in the ancient temples of health." That great author, the prince of physicians, as he was called, I think, by Pliny, gathered much of his knowledge at the Æsclepon of Cos, one of the most famous, as I have already said, a few centuries before the Christian era, and, of course, covered forever with éclat by its illustrious alumnus.

Æsculapius was married, as every respectable physician should be, and as was desirable in an exemplar, the father of six children, two sons and four daughters, of whom both the former, Podalirius and Machaon, taught by their "parent god," were "famed surgeons," "divine professors of the healing arts," according to Homer, in the Trojan war, and of the latter, one, Hygeia, became the goddess of health. Hippocrates probably traced his pedigree to Podalirius.

I have said that a goat was frequently sacrificed to Æsculapius. This was most often done by the Cyrenians. A more common sacrifice was the domestic cock, a very watchful bird, a fit symbol in medicine. Socrates has, through Plato,* made this memorable. Said the dying sage, as he felt his limbs grow cold: "When the poison reaches the heart, that will be the end." Feeling his body gradually losing its vital heat, and realizing that relief from his troubles was at hand, he said (they were his last words): "Crito, I owe a cock to Æsculapius; will you remember to pay the debt?" "The debt shall be paid," responded his friend.

There is yet another symbol connected with figures of Æsculapius, to which reference has been already made, about which I must say a few words. I refer to the child Telesphorus, likely a sort of genius or

FIG. 6.

dæmon, such as that of Socrates. A cut (Fig. 6), copied from Tooke,† minus the laurel branches,

in which he appears wrapped in a mantle, is given. He is barefooted. Figures of him vary considerably in appearance. He is generally regarded as symbolic of the sustaining vital force, the *vis medicatrix nature*, upon which greatly depends the recovery of the sick.

Health is symbolized in Hygeia, the pretty

"Daughter of Pæon,* queen of every joy,"

to use the appropriate words with which Armstrong starts off in the invocation to her, at the beginning of his fine poem.† At least one figure of the goddess is doubtless familiar to my readers, that in which she is represented as a blooming maid with a serpent twined around one of her arms, and feeding out of a patina, or chalice. Referring to this ideal, Dr. Aitken Meigs, who died too young, in a remarkable farewell address to students, delivered in 1879, pronounces "the high-born maid" to be

"Of beauty's types the highest, best idea,"

and continues:

"Nor fragile she. nor pale, but ruddy, strong,
And gladsome as a tuneful, joyous song;
Her comely form, in swelling curves designed,
Is perfect grace, with glowing strength combined;
Crimson and white in her fair face contend,
Upon her cheeks in sweet confusion blend;
Her rosy lips excel the coral's brightness,
Brow, nose and chin are fleecy ways of whiteness;
Loose flowing falls her hair, a golden spray.
Forth from her lustrous eyes, she scatters day.

* * * * *

In one small hand a cup she deftly holds,
Whist round her soft, white arm in many folds
A serpent twines, and from the chalice drinks.
Low crouches, sometimes, at her feet, a sphinx.
From these strange emblems learn her character;
How very cunning she, and how exact her
Knowledge and profound; how with wondrous skill
Her youth renews; and is discreet and still."

Dr. Meigs not inaptly says that this is to the physician what the chosen maid was to the knight of old, the patron saint. He believes that "in all probability Hygeia is derived from Mant or Mut, 'the mother goddess' of Egypt," as well as that "Æsculapius is doubtless the Egyptian Thoth, or Hermes Trismegistus, whose symbols,

* Pæon, or Pæon, was the name frequently given, after the time of Homer, to Æsculapius, as well as his father (Apollo). It is the one always used by Homer in speaking of the physician of the Olympian gods. Thus in reference to the source of the medical knowledge of the Pharian or Egyptian race, it is said (Odyssey, b. iv.):

"From Phæon sprung, their patron-god imparts

To all the Pharian race, his healing arts."

"Pæonian herbs" is the phrase made use of by Virgil (Æneid, b. vii.) in his account of the restoration to life of Hippolytus, and elsewhere.

‡ The Art of Preserving Life.

* Phædo.

† Op. cit.

the staff and twining serpent, surmounted with the mystic hawk of Horus Ra and the solar uræus, appear in the ancient temple Pseleis, near Dakkeh, in Nubia."* The explanation of the symbols connected with the figure of the goddess given is all very well, except, perhaps, in regard to the import of the serpent. Taking the reptile to be symbolic of the art of healing, why it should be connected with the goddess of health is not very obvious. In this connection its presence may possibly imply that it is only through medical knowledge that health can be preserved. The chalice is not always present, and as indicated in the verses, neither is the sphinx. I will give a

FIG. 7.

cut of the goddess copied from DeWilde's book, in the attractive form in which she appeared on an antique gem (Fig. 7). One might raise the objection that the serpent is too long to be of the Æsculapian species.

I have said that the cut of the goddess given is from a gem; and a very appropriate thing it would be on, say, the seal ring of a physician.

And this reminds me that a ring was from the earliest times, and until recently, regarded as a necessary item of the insignia of the medical man, one of the indispensable things to have in order to be suitably prepared to justly exercise the healing art. It is spoken of, I believe, in one of the spurious Hippocratic works. Different stones in it differently engraved gave it different uses and powers. Another item of the insignia referred to was the gold-headed cane. As seen in the last century, it was smooth and varnished. The gold head may have had some significance; it was at least suggestive of the physician's reputed love of the precious metal. It will be

remembered that in the famous description* of his doctor, Chaucer says, and with charming casuistry:

"For gould in physike is a cordial;
Therefore he lovede gould in special."

Carrying a gem, whether in a ring or otherwise, with a symbol of health engraved on it, was, of course, a superstitious practice—a practice not at all objectionable, if it inspires hope and fortitude. Many a wise man, however, has carried a symbol of health, to serve to preserve his own, just as many a one has worn a red string around his neck to keep off small-pox, or gone about his business with a chestnut in his pocket to prevent an attack of rheumatism. This plan of holding diseases at bay inspired the making of many symbols of medical significance; that is, medical amulets. The abraxas stones, of which much has been said, were largely such. On each there was generally some figure or inscription together with the word ABRAXAS,† which constituted the characteristic feature.‡ The Greek letters of this mystic word equaled in numerical value,|| 365, the number of days in a year. A cut of one of these stones is given by Sharpe.§ After speaking of the serpent of evil on it, he continues: "Underneath it is written the magical word abraxas, *hurt me not*, an Egyptian word which the Greeks made use of as believing that the evil spirits were better acquainted with the Egyptian language than with the Greek."¶ Not a few believe that the word is not such at all. At any rate, the abraxas stones are believed to have originated with the Basilidean Gnostics. Large numbers of them have been found in Egypt, Spain and elsewhere. I may add here, that in De Wilde's book a talismanic gem is pictured, on one side of which are the Greek letters ΙΑΩ, signifying God; and on the other a representation of an extremely *erotic* and rather misshapen lion rampant, which worn in a ring was said to prevent renal and other diseases. De Wilde observes, and in accordance with a belief of ancient date, which I cannot dwell on,¶ that

* Canterbury Tales.

† This should not be confounded with the word ABRACADABRA, which, however, was long reputed to be of great efficacy when brought to bear against agues and other fevers.

‡ The cut of one at the end of this article is copied from an engraving of one in De Wilde's book. On the reverse side was shown a lion with a prey in his mouth, and a star between his legs.

|| The first, letter 1; the second, 2; the third, 100; the fourth, 1; the fifth, 200; the sixth, 1; and the seventh, 60.

§ Op. cit.

¶ On second thought, I deem it wise to add a note on this curious and important matter. The *linga* of the Hindus

* Hygeia may have sprung into existence as a personification of the great serpent-accompanied virgin, river-mist or cloud goddess, Pallas Athene (Minerva) in her capacity of Healer. The Egyptian goddess corresponding with Minerva was Neit or Neith, the great mother who gave birth to the sun-god, Ra, and the tutelar goddess of Sais. As to the Egyptian god corresponding with Æsculapius, Dr. Erasmus Wilson, in his "Egypt of the Past," says: "Imhotep, the Imuthes of the Greeks, corresponded with their Æsculapius." Imhotep was a king of the sixth dynasty. He was the son of Ptah and Sekhet. Ptah, the father of the gods and the great artificer of the world, has been taken to correspond with Vulcan (Hephestus), who had the gift of healing.

in this one was health symbolized; says he: "Leo erectus verum signum sanitatis protendit."

I might go on and speak of that peculiar symbol placed at the head of prescriptions, and taken by the practical physician to mean *Recipe*, but which is a symbol of Jupiter, whose good influence was, in other days, generally invoked when remedies were prescribed—and the physician's color, yellow, with others, such as the red-striped pole, now regarded as the symbol of the mere barber, and the skull and cross-bones—but enough has been said to give some idea of the scope of medical symbolism. In extent it is evidently not very limited, nor is it without variety and the means of variety enough. Yet, how little use does one see made of it! How seldom do publishers take any advantage whatever of it on the covers of their books or anywhere else! And what little is here and there attempted is apt to be a trifle preposterous, on a par almost with the misuse of the serpent by the quack-medicine man who confounds the religious (Christian) significance of it with the medical. Here is a medical publisher who makes use of the caduceus of Mercury, there one the club of Hercules with a rather venomous-looking snake crawling down it from—heaven only knows where—and so on. And there I see a

the *phallus* of the Greeks, and the *penis* of the Romans, in the form of an "upright" sacred tree, or tree of life, named by the Jews *asherah* (vide Rawlinson's "Ancient Monarchies," Vol. II.), and mistranslated, perhaps purposely, in the Bible, *grove*, as in the phrase, "where the women wove hangings for the grove" (2 Judges xxiii. 7), appeared on the circular altar of Baal-peor of the Moabites and Midianites, and some of the Israelites (vide Numbers xxv. and 2 Judges xxii.)—the Triapus of the Greeks and Romans. This object has been taken by many peoples as symbolic of the widely worshiped, active, renewing, generative power in nature, the sun, called Horus by the Egyptians, Asshur by the Assyrians, Baal by the Phœnicians, Apollo by the Greeks, etc., just as an oval or round figure, the *yoni* of the Hindus and the *cleis* of the Greeks, has been of the passive power, the earth. "As such," says Cox, in his philosophic work, already quoted from, "the symbol became a protecting power, like the Palladium which guarded the city of Troy, the rod or staff of wealth placed in the hands of Hermes, the budding thyrsus of the worshippers of Dionysus, and the sistrum of the Egyptian priests. The rod thus grew into a tree of life, and in conjunction with the oval emblem became the stauros or cross of Osiris, the Egyptian symbol of immortality, the god himself being crucified to the tree, which denoted his fructifying power." "When we add," says the same author, "that from its physical characteristics the *asherah* suggested the emblem of the serpent, we have the key to the tree and serpent worship." The tree worshipped was an upright statue or post, occasionally with sprouts. The phallus-serpent was never regarded with dread, or looked on as other than a beneficent and life-giving power.

In accordance with these ideas, both the serpent and staff of Æsculapius may have been of phallic origin.

journal devoted to anatomy and surgery with a seal on its back, in which appear heads of Vesalius and Paré, an emblem of anatomy and surgery, about as expressive and appropriate as one consisting of heads of Washington and Bismarck would be of war and conquest. But perhaps a little, even if bad, is better than nothing. Anything modern that is worthy of attention is rare. I may take note of a fair specimen.

On the title-page of a journal edited by the late Dr. Dunglison, a learned and sensible man, *The American Medical Intelligencer*, which had a brief existence in the latter half of the fourth decade of this century, appears the symbol, the cut of which is given (Fig. 8). The idea is obvious and is good, but is poorly executed.

FIG. 8.

Ideas for symbolic designs of medical significance are plentiful enough. The instruments and drugs used by the disciples of Æsculapius afford a host, if one does not wish to take advantage of mythological or allied hints. If it be desired to give an Egyptian design on the cover of a book, say on obstetrics, the main part of an admirable one may be found ready at hand on the wall of the great temple at Luxor.* It is the scene, and a sufficiently chaste one, of the maiden mother giving birth to the future king, Amunotoph III., for whom the temple or palace was erected about 1400 B. C. She is seated on the midwife's stool, as described in Exodus i. 16, while two nurses have her by the hands, doing what they can to ease the pains of labor. But for a design of obstetrical import there could probably be few better than one in which prominence were given to the good housewifery symbols, the pestle, hatchet, and broom: those respectively of Pilumnus, a god of children; ntercidona, the goddess who first taught the art of cutting fire-wood; and Deverra, the goddess who invented the broom, that great instrument of cleanliness, and enemy of that Python, or I may say Hydra, of many modern doctors, the disease-germ; the deities that save the pregnant woman from harm from her special enemies, the unclean sylvan gods. The broom! wise old Romans! wiser than the moderns with bottles of carbolic acid in their hands. And with these symbols, especially if the design were wanted for a work on obstetrics by a female author, there might be given a figure of

* Vide Sharpe's "Egyptian Mythology."

the goddess Juno Lucina, the special friend of women in labor. Or if the author had no respect for the classic divinities, and had faith enough in magical healers, a figure of—I need not mention whom, for I fear it would be hard to find a modern doctor who has regard enough for these traditional heroes to desire to place the image of one, even if an old specialist of great renown, on the back of his book.

By way of conclusion and at the risk of running too deep into occult knowledge, I will give some account of a remarkable magic figure, of interest to the physician, about which little is generally known, but which is often referred to in certain out-of-the-way lines of study. I refer to the pentacle, triple triangle, or pentalpha of Pythagoras, the formulator of a celebrated system of philosophy, the basis of which is numerical.* A

Fig. 9.

representation of it in its simple form is given herewith (Fig. 9); and it will be observed on inspection that it has five arms or points, five double triangles, with five acute angles within, and five obtuse ones without; so that if there is the virtue in the number five which the occult philosophers have asserted there is, it must have much. It is in fact the famous legendary key of Solomon, which has played a notable role in history. Tennyson,† one of the few well-known authors by whom reference to it is made, speaks of it when he makes one of his characters (Katie) draw (it can be done through one stroke),

"With her slender pointed foot
Some figure, like a wizard's pentagram,
On garden gravel."

I have said that little is generally known about the pentacle. Here is some evidence. Ruskin‡ defines it to be "a five-pointed star or a double triangle ornament, the symbol of the trinity," a wrong definition, but not quite so bad as that given in Mollett's handsome new work,§ namely, "a figure formed of two triangles intersected so as to form a six-pointed star." The opinion is expressed by Bayard Taylor,§ that the magical powers attributed to it could be explained by the fact that being made up of three triangles, it was a "triple symbol of the trinity." This might be true, but it was regarded as possessing mysterious powers long before Christianity originated.

* Vide The Pythagorean Triangle, by George Oliver.

† The Brook.

§ Dictionary of words used in art and archaeology.

‡ In his notes to "Faust."

A common mistake, the one evidently made by Mollett, of even learned writers, as for example, Oliver* and Fairholt,† is to confound the pentacle with the seal of Solomon or David, which consists of two deltas or equilateral triangles, so arranged as to form a six-pointed star.

By the German writers on magic and kindred subjects, the pentacle is often called *Drudenfuss* (wizard's foot), a term which Mackey‡ takes to be a corruption of the term for Druid's foot, by which people it was in use, being often worn on their sandals. As Bayard Taylor, however, says: "*Drud*, from the same root as *Druid*, was the old German word for wizard."

This symbol has been extensively as well as long used. It has been observed on a figure of Anubis in Egypt. It is stated|| that it was used on coins of Antiochus Epiphanes, and also§ of Lysimachus. The statement I have seen made somewhere, that it is one of the old sect-marks of the Hindus, is an error, I believe. By referring to Coleman's¶ or Birdwood's** work, it will be seen that it is Solomon's seal that has been so used.

The pentacle has been accorded great potency and extensively used, to keep off witches and all sorts of evil influences, including the devil himself, and hence has served purposes very similar to those to which the horse-shoe has often been put. Aubrey†† says that it was formerly used by the Greek Christians as the sign of the cross is now, "at the beginning of letters or books, for good luck's sake"—something which old John Evelyn was wont to do in his books, and as Southey placed the puzzling monogram,‡‡ meant, perhaps, to have similar significance, on the title-page of his work, "The Doctor." It may be seen on many a cradle and threshold at the present day in the Fatherland. The readers of Goethe's great work||| will remember that Dr. Faust had one on his threshold, and that when he began to perceive that there was something suspicious about

the character of the "poodle," he remarked that,

"Für solche halbe Höllenbrut
Ist Salomonis Schlüssel gut."

How he got in, Mephistopheles himself afterwards explained by showing that one of the angles of the "Drudenfuss" was left open.

Disciples of the Samian sage, Cabalistic Jews and Arabians, and others, long regarded the pentacle as a symbol of health, and made use of it as a talisman, calling it Hygeia, the name of the goddess of health. It was so-called, and to some extent likely for a similar reason, regarded as a sacred symbol of health, because it could be resolved, it was believed, into the Greek letters which form the word Hygeia, and these letters* were placed one on each arm of the figure, as is done in the one † at the head of this article. It was regarded, in fact, as a sort of rebus of the name of the celebrated daughter of Æsculapius.

The scholarly and ingenious readers of the REPORTER may be able to trace more or less definitely this traditional similarity. It is an interesting point about what is certainly a very remarkable figure.

NON-CONSUMPTION OF FATS BY PHTHISICAL PATIENTS.

BY G. W. JOHNSON, M. D.,
Of Savanna, Ill.

The writer in a limited way, such as falls to the lot of a country practitioner, has observed among all his phthysical patients, without an exception, an aversion during their entire lives to the consumption of fats. The peculiarity is observable, as in the nursery rhyme of "Old Jack Sprat, who could eat no fat, and his wife who could eat no

lean," among people generally, that while many enjoy fatty food, eating a large proportion of fat with their meat, or even taking a mouthful wholly of fat, others carefully exclude everything except the muscle, the taste and idea of eating fat being repugnant in the extreme.

My object in calling attention to this matter, is to direct the attention of others to the subject, and ascertain if their observation has been in accord with mine.

I have been so uniformly impressed with the fact, that I often make use of it as an aid to diagnosis, and when a patient presents him or herself, for advice, with symptoms which are suspicious, and look rather toward tuberculosis, and the patient is quite anxious as to the result of the trouble, and I can, on making inquiry, ascertain that they are lovers and eaters of fat, I feel a reasonable sense of security, and give them encouragement to hope for a happy termination of their difficulty.

It is well known that fats, especially cod liver oil, have a powerful influence for good, when administered to consumptive patients, this form of fat only being selected because of its easy assimilation. Would not good fat beef taken *ad libitum*, be equally efficient, granting that it be properly digested and assimilated?

Coming as I do from tubercular stock, having lost three sisters, one brother, and numerous cousins and other relatives from consumption, I have had a chance to notice the fact that in their cases they all were eaters of lean meat only, while my father, through whom the predisposition seems to have been transmitted, escaped, and died at the age of 88 years, of other disease, and had been a lover and eater of fats.

Bennett, in Reynolds' practice (page 121, Vol. II), says: "An observation of the peculiar dyspepsia which so frequently accompanies tubercular disease, will satisfy the observer that it depends upon excess of acidity in the alimentary canal, which favors the solution of the albuminous and mineral matters, but is opposed to the emulsionizing of fat. It is the non-assimilation of fatty elements of food, and their diminution in the blood while the albuminous elements are comparatively in excess, that gradually interferes with nutrition; the molecular basis of the chyle is impoverished, the elementary molecules so necessary for the formation of healthy blood corpuscles are diminished, the liquor sanguinis consequently is poor in fat and rich in albumen, the entire growth of the constitution as a result is affected, and its powers rendered weak."

* Sometimes the synonymous Roman name, Salus, was so used. In Mrs. Palliser's work, already referred to, it is thus seen. It is there spoken of as a device used by Marguerite of France, wife of Henry IV., and the last of the Valois.

† This, as shown, forms one side of a "charm" of the writer's. It is of Masonic as well as medical and Christian in port, at least in its outline, and has an appropriate emblem of the kind on the other side.

The view here taken seems to be that it is a failure to digest owing to the "peculiar dyspepsia," rather than a natural repugnance to fats, which causes the difficulty.

I claim it to be largely a matter of taste, which might, and ought, to be corrected before the "peculiar dyspepsia" makes its appearance; let the young be encouraged to eat more fats, and protect their constitutions against being made weak by liquor sanguinis impoverished in fatty principles.

My first advice given to suspected cases is: cultivate a taste for, and eat as large a proportion of fatty food as possible, and by so doing escape the necessity for the nauseous cod-liver oil, which otherwise would soon be imperatively demanded.

If the eating of fat from childhood is a prophylactic of recognized worth, while the entire materia medica is vainly brought into requisition to stay the progress of the once-developed disease, it seems an easy matter to decide which is of the most importance.

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL.

BY WILLIAM PEPPER, M. D., LL. D.,

One of the Physicians to the Hospital, and Professor of Clinical Medicine in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M. D.

The Treatment of Epilepsy. *Clinic*

By Prof. Pepper

GENTLEMEN: I shall to-day call your attention to ~~two~~ two men, who are suffering from epilepsy. In a hospital of this kind, we see the most unfavorable cases of this disease, for the sufferers rarely come to us until they have had a variety of treatment outside, and until the physical and mental condition has become seriously impaired by the disease. Although an institution of this character is one of the worst places for the study of the therapeutics of epilepsy, there is no better place for the study of the symptomatology, pathology, and diagnosis of the disease. I want you in the very beginning of our consideration of these cases to disabuse your minds of the idea that epilepsy is an incurable affection. In many cases it is incurable, yet there are many cases which are very amenable to treatment, epilepsy being, in truth, one of the most varied of diseases; varying in its gravity from a comparatively tractable condition, to a condition which is absolutely irremediable. I shall make the two cases before you a text for some practical remarks on the treatment of this disease.

This young man, a native of England, was healthy up to the age of four years, when he suddenly lost consciousness, and fell over, while sit-

ting at the table. One year afterward, the convulsion returned, and from this time he has been the prey of epileptic seizures, occurring at varying intervals. This is a bad case. It has been noted that he has had as many as one hundred and twenty convulsions in twenty-four hours. He states that when fourteen years old he fell into a trance, lasting for two or three days. After this, he enjoyed freedom from the epileptic attacks for two or three years. About five years ago hemiplegia of the left side came on. This has gradually improved, but the arm and leg are still paralyzed to a certain extent. In walking, he drags his leg in a clumsy way, after the fashion of an old hemiplegic. The muscles of the shoulder and arm still retain some power, but the flexor and extensor muscles of the hand are almost completely paralyzed.

The attacks are somewhat controlled by bromide of potassium and hydrobromic acid. He thinks that he has been improved by treatment. His memory has become much weakened, and all his statements must be taken with a certain degree of allowance. There is no evidence of fracture of the skull, and no history of his having received such an injury. The attacks are of the character of ordinary epileptic fits. The patient is taken suddenly, cries out, falls in a state of spasm, bites his tongue, froths at the mouth; the convulsions cease, and he passes into a state of coma, with heavy respiration. After a time, he comes out of this, seems dazed for a little while, and gradually returns to his usual condition. As is always the case with epileptic attacks, these spells occur at irregular intervals. He has gone considerable periods, he states as long as two or three years, without having an attack, while at other times they have come with great frequency. This irregularity is characteristic of the disease. Sometimes a cause which has served to provoke the attack may be found in indiscretion of diet, excitement, fatigue; but sometimes without apparent cause after the attacks have been occurring at intervals, there will be a group of fits after this, the spells may not again appear for a considerable time. I dwell upon this because it will be of importance when we come to consider the treatment, as showing how difficult it is to decide the effect of any line of treatment.

This second man is a machinist. He never had a fit until he was thirty-three years old. It came on suddenly, while he was at work. This man's memory appears to be good, so that we can depend on his statements. The attacks recurred at first at intervals of two or three weeks. Under treatment they became less frequent, but when treatment was stopped they increased in frequency. He has gone as long as four months without an attack, but they have never been entirely arrested. Immediately after the attack he passes into a state of mania, lasting from fifteen to thirty minutes. The attacks may be described as follows: He falls, froths at the mouth, works in a general convulsion, and sometimes bites his tongue. This lasts a minute or more; he then passes into a state of aggressive mania, throwing his arms and striking in a blind way around, injuring any one who happens to be near. His last paroxysm was on the fifteenth of August, three months ago, when he had a severe general convulsion, followed by

screaming, working of all parts of his body, and had to be held by several attendants. When asked where he felt bad, he said in his head, and screamed violently as though suffering greatly.

This case represents another form of epilepsy, and one more rare than that illustrated by the first patient. In the majority of cases, the disease shows itself in some form during childhood, or if the disease itself does not appear, the child will show a tendency to it. For instance, the child will have one or two convulsions when teething, or at the beginning of an attack of measles or scarlet fever, and after teething is over or these attacks of acute disease have passed away, the child will have no spontaneous convulsions for a number of years, and the parents will have entirely forgotten the circumstance, until the age of seven, eight or nine arriving, the child, without apparent cause, will again have a convulsion, and from that time be a confirmed epileptic. Such is very commonly the history. Still more usual is it for the occurrence of some accident to arouse this tendency to convulsion; for instance, a child who had shown this convulsive tendency in infancy, but which has apparently passed away, will have a fall, striking its head, and after that convulsions will be developed. This fall need not be followed by depressed fracture or symptoms of such severity as to suggest the production of meningitis; but merely a fall, giving a severe shock to the nervous system, such as many children may have without the development of such convulsions, and yet in these children, owing to the exaggerated tendency, the occurrence of convulsions will be established, and will pass into a habitual state. I suppose the fact is that every one is liable to have convulsions, which may be developed by an exciting cause of sufficient severity; but where, as in some, the tone of the nervous system and the hold which the vaso-motor nerves have over the circulation, is so strong and well sustained, that it seems impossible for any shock, mental or physical, to overcome it and throw the system into convulsions, in others a moderately severe, and in others a trifling shock, is able to produce this effect. In another class the tendency is so great that the convulsions occur from the most trivial causes, as fatigue, excitement, indiscretion in diet, or other form of reflex irritation. We recognize then, varying degrees in the tendency to convulsions, from the slight degree which has to be called into view by some powerful cause, up to the marked predisposition which is so intense that the slightest cause suffices to arouse it.

Before going on to speak of the form of epilepsy illustrated by this second patient, let me speak of some of the practical points in reference to these cases and the lines of treatment which grow out of them. In the first place, recognizing that this disease is merely an expression of the tendency of the nervous system to lose control of itself under provoking causes, you will search in these children for exciting causes. You will also seek for predisposing causes.

Among the predisposing causes, inheritance is a powerful one. When a child comes of a family of strongly marked nervous temperament, if several members of the family have exhibited symptoms of nervous disturbance, and if the child began at an early age to show a tendency to irregular

nervous manifestations, the probability is that there is such a profound morbid tendency of the nervous system, that no effort will control or eradicate it. Another predisposing cause is long continued exhausting illness. This may excite a tendency to convulsions at any age. A short time ago, a lady consulted me and gave the following history: she had been perfectly well up to five years ago, when she had a very severe attack of typhoid fever. This was complicated with hemorrhages, phlegmasia alba dolens of both legs, and relapses of fever, keeping her in bed for four months. After this passed away, and after she began to go about, she had a convulsion following some unusual exertion. For three years convulsions of an epileptic character continued, recurring at varying intervals, sometimes as frequently as twice a week, and at times being so severe as to require the strength of two persons to restrain her. Gradually, as her health improved, the attacks became less severe and less frequent. For the last six or eight months she has had no general convulsion, but has had periods of momentary oblivion, attended with severe pain in the region of the heart. She is evidently outgrowing the convulsive tendency, which was called into activity by the violent attack of typhoid fever. Last week I saw in consultation a case of the same character; a case of typhoid fever with severe hemorrhages leaving the patient in a state of the greatest debility. After the fever had subsided, the patient had a severe convulsive attack. Unless great care is taken I have no doubt that the convulsive tendency will show itself in that patient just as it did in the woman to whom I have referred. Where there has been no inherited tendency, and where the child has not shown a disposition to convulsions, these attacks after protracted disease are not of so unfavorable omen, as where they come on in consequence of a constitutional tendency.

I need not say to you that accidents in childhood often produce this tendency. It is exceedingly difficult to make the prognosis in such cases. Children so frequently meet with accidents, that it is exceedingly difficult to say whether the convulsions have resulted from a blow, or whether the child has an inherited tendency which is just showing itself. Still you will be pressed for an opinion by the parents. If there is any actual injury, such as a depressed fracture, or if the accident were followed by unconsciousness and paralysis or mental affection showing that the cortex of the brain had been involved, you will have no hesitation in expressing the opinion that some injury has been done, and according to the seriousness of the injury and its curable character, will be the prognosis. More frequently, however, you will be forced to conclude that the shock to the nervous system has excited the convulsions. If the injury has been slight, the prognosis is bad; but if the injury has been severe, the prognosis is more favorable. If there is evidence of permanent injury to the brain, the prognosis is of course unfavorable. In the case of this boy, I cannot say whether or not he has had a hurt, but we have in the hemiplegia evidence of serious intra-cranial disease. There has been in all probability, a lesion either in the corpus striatum or in the cortical centres corresponding to

the muscles of the left side, which has left behind it a loss of substance and a cicatricial condition of the brain itself, which is incurable. I should, therefore, in this case have no hope of eradicating the tendency to convulsions. It will be kept up perpetually by the organic lesion of the brain which exists.

A short time ago I showed the results of a post-mortem in the case of a physician who many years ago was thrown from his buggy, his head striking against a tree, causing a depressed fracture of the internal table of the frontal bone over the right eye. He immediately had coma, which lasted for two or three days. He recovered, and was apparently perfectly well from 1860, when the accident occurred, until 1881. He served in the army during 1881, and reached the rank of full surgeon. After leaving the army, he settled in a Southern town, built up a good practice, and laid by some money. He then moved North, buying a good practice in one of the towns of Pennsylvania. In 1881 he began having convulsions of intense severity, recurring at long intervals. When the case came under my observation, some eighteen months ago, it gave rise to some embarrassing questions. Had there been an injury to the bone so long as twenty years previously, which had remained dormant, and was there now developing some slow lesion near the seat of injury, the result of this hurt; or had the shock to the nervous system, causing the coma and unconsciousness, left no serious lesion, but now, in consequence of overwork and depressing influences, had there been a revival of this tendency without actual disease, and should we trephine this man or not? For a time we decided not to trephine; but the convulsions continuing, we did trephine, but it did no good; the convulsions continued, and the man died. The autopsy revealed an abscess in the anterior lobe of the right hemisphere, with a secondary abscess in the anterior lobe of the left side. There can be little doubt that a slow, irritative lesion had existed during all these years, and the brain became habituated to its presence; and it was not until a large area of the brain became involved, that the system responded to its influence and convulsions made their appearance.

In children with convulsions, where there is a history of an injury with perhaps some lesion of the head, you will often find it difficult to decide whether or not any operative interference should be adopted. Usually you will find that you cannot decide upon having the head trephined. Yet I am satisfied that we ought to trephine the head for epilepsy more frequently than we do. Whenever there is a lesion of the cranial walls, although there may be no depressed fracture, where there is possibly some lesion of the membranes, and where the convulsions cannot be controlled, my judgment would be strongly in favor of trephining. I have seen some most excellent results follow this treatment. The lives of these patients are so sad, and so sadden the lives of those around them, that although we may to a certain extent control the attacks, yet this is not very satisfactory, and therefore the chance of obtaining a radical cure is worth a good deal of risk.

Another and extremely difficult question comes up in the treatment of young children, such as

this lad was fifteen years ago, and that is the question of intellectual development and training. A child of five or six is attacked with epilepsy. Such children are often among the brightest and most intelligent, and frequently are even precocious in their intellectual development. Yet it is clear that if the brain becomes excited by study, too much reading, or violent play, the convulsions will become more severe and frequent. In presenting this question to parents, they have argued that it was better to allow the child to continue at school, for if allowed to grow up ignorant, and without mental training, he would, if shut out from the world by reason of his disease, be unable to occupy his mind, and might readily fall into vicious habits; and if the attacks should be relieved, he would, in consequence of his want of education, be unable to take his place in life. Therefore they have argued that it was better to take the chances of keeping up the disease than to allow the child to grow up in ignorance. To decide how far we should interfere with intellectual work, and how far the advantages of such interference counterbalances its disadvantages, is one of the most difficult problems to solve. My own judgment is decidedly against allowing these children to study or go to school. If taught, they should be taught at home, and emulation, ambition, and excitement of every kind should be studiously avoided. They should be taught, as far as it is proper to teach them, at home and not in schools. Specious as are the arguments pressed upon you by the parents against this plan, the results of yielding are usually bad. Epilepsy, even when taken at the earliest period, is not a disease which in my experience has been cured by drugs alone. When I have succeeded in eradicating this tendency, and the cases are not rare in which success has been attained, it has not been by drugs alone. It has been by the regulation of diet, regimen, and hygiene, and secondarily by drugs. But allowing the child to go to school, and when the convulsions become more frequent, increasing the dose of bromide of potassium, and when that loses its effect, changing to bromide of calcium, bromide of lithium, or hydrobromic acid, can have only one ending—and that is the enfeeblement of the whole nature of the patient, mental, moral, and physical, and the settling upon him of a hopeless bromide habit, without eradicating the epilepsy. There are some few cases in which a radical cure can be effected by drugs. There is a larger number of cases where with proper hygiene and the continued use of suitable remedies, the disease can be kept in check indefinitely. There is a still larger number of cases, and this may be said of almost all cases, in which if you depend upon drugs alone, and do not pay the first and closest attention to the regulation of every point of the daily life, you will find that the case goes from bad to worse, and that the effect of the drugs has been bad, without influencing the disease. There is an enormous amount of damage done by the way in which bromides are used in convulsive affections.

~~This question of the intellectual training and development requires the most careful consideration. The child requires a certain amount of training, and should be encouraged to use its mind in certain ways, for this exerts a beneficial~~

and tonic influence. As I have said, the stimulus of competition, as in schools, is always an injury. I can see no other explanation of these cases than that there is a state of febleness of the nerve-centres, whether congenital or acquired; and what is true of them is also true of adults, although to a less extent. These children, therefore, require a totally different arrangement of their daily life from that of healthy children. It should be based upon the fact that they are suffering from nervous prostration as well as nervous irritation. Of course, if the child has a positive lesion of the brain, we recognize that as a sufficient cause of the irritation and convulsions. In speaking thus I do not allude to those cases in which some source of reflex irritation has been allowed to continue and keep up the convulsions, but where, after the removal of all causes, the child continues to have convulsions. Such a child seems to me to be suffering from nervous prostration in a very real sense, and I think that the best results will be obtained by treating the child for that condition.

I should regulate the life of such a child in the following way: Go to bed at seven o'clock, and lie in bed until eleven o'clock in the morning; take a walk, come in and study, dine; after dinner, play or walk again, then rest and retire at the hour mentioned. Sometimes this can be carried out; at other times the child is so restless that any attempt to enforce such rules will do more harm than good. Where the child can be restrained, I regard prolonged rest in bed as one of the most useful adjuncts to the treatment of juvenile epilepsy. I have seen remarkable results follow this line of treatment. I recall a case in which I suppose a cure has been effected, for it has been a year since the child has had a convulsion. The patient was a boy, born of nervous parents, a boy of brilliant intellect, and ambitious in every way. He had convulsions while teething, and at the beginning of an attack of scarlet fever, when three years of age. He had grown well and appeared perfectly healthy up to the age of eight, when the epileptic attacks made their appearance. They proved obstinate and violent. He was removed from school and sent to a farm, allowed to play out-of-doors, and took bromides in moderation. The convulsions soon stopped, and for six or seven months he was free from them. He was regarded as cured, came home, went to school, and the same thing happened again. The fits proved intractable. They became severe and recurred with increasing frequency. He was again sent to the country, but this did no good, I decided to adopt more radical measures. I persuaded him to go to bed, and kept him in bed for three months constantly. During this time he took moderate doses of the bromides, and his diet was regulated with extreme care. The convulsions occurred less and less frequently, and finally stopped entirely, and he had none for several weeks. He was then allowed to get up for an hour each day. The length of time out of bed was gradually increased until he returned to his ordinary mode of life. He has not yet been allowed to return to school. I have seen this same result in many other cases.

The hour has nearly expired, and I shall, therefore, allude to only one more point to-day,

and it is one about which much has been said of late; that is the question of genital irritation, as provoking attacks of epilepsy. I think that too much attention and importance has been given to this point. I think that you will be doomed to disappointment, if you expect to have a great deal of good follow the circumcision of adherent and contracted prepuces, which is the most common expression of genital irritation. In the female, there are few local causes of irritation of the genitals. I know that there are cases in which an adherent prepuce with irritation of the mucous membrane has excited the convulsion, and after the removal of this cause, no other convulsions have appeared. Far more commonly, it will be found that children who, with an adherent prepuce, get convulsions, are epileptics in whom that may be one of the exciting causes, and although this may be removed, it will leave behind the epileptic tendency, and convulsions will occur from some other cause. In the case of the boy to whom I have referred, there is a contracted prepuce which I was anxious to remove, but the parents refused and the child has gotten well without the operation. In some cases, after the operation of circumcision, complete relief has followed; but in a larger number of cases, the condition of the prepuce has been found to be only one of the elements of irritation.

The same thing is true of worms in the intestinal canal. This is a rare cause, and still more rarely is it the only cause of irritation. We should, of course, carefully search for these causes of external irritation, and remove them, and above all, as far more important, should we see to it that there shall be no condition of intestinal irritation.

I shall devote the next hour to the consideration of epilepsy coming on in adults, and to the use of drugs in this disease.

(To be continued.)

NEW YORK HOSPITAL.

CLINIC OF PROF. WILLIAM H. DRAPER.

Reported by W. H. SEELYE, A. M., M. D.

Traumatic Peritonitis.

GENTLEMEN: I want to give you the termination of the case of traumatic peritonitis which you saw here last Thursday (see REPORTER, vol. L., p. 12). It came to a fatal issue that night, death being preceded by a rising temperature, which finally reached the somewhat unusual point of 109° and a fraction. At the post-mortem examination there was found a rupture of the ilium at a point nine inches from the cæcum. This is in accordance with the suspicion which I had of the cause of the peritonitis, the pain and tenderness being too severe to be due to a peritonitis resulting from a simple contusion of the abdominal walls. The rupture had extended through all the coats of the intestine, and there were several ounces of a sero-sanguinous fluid found in the peritoneal cavity.

—Dr. and Mrs. Hiram Corson, of Plymouth, have celebrated their golden wedding.

Large Intestines from Two Cases of Chronic Dysentery, one of them Showing Pseudo-Polypi.

BY J. H. MUSSER, M. D.

Case 1. The patient had chronic dysentery; further clinical information cannot be given. No record of autopsy preserved. The specimen is from the museum of the Presbyterian hospital, and I present it to-night on account of its rarity. It is a part of the large intestine, fourteen inches long. To the naked eye it shows thickening of the mucous and sub-mucous layers, and hypertrophy of the muscular layer. On the surface of the mucous coat innumerable polypoid growths are observed, some pedunculated, some sessile. The sessile growths are from the size of a millet seed to that of a chestnut, round or ovoid. The others also vary in size from a pea to a large bean; their pedicle is generally a one-sixteenth to one-eighth of an inch long. The reporter remembers seeing the specimen when recently removed, and knows there were more pseudo-polypi than are here visible, many having fallen off from handling, etc.; that there was scarcely any healthy mucous membrane; that in this part of the intestine, there was almost complete ulceration of the mucous coat. At one point a large stellate cicatrix, depressed in the centre, is noticeable, while all over the surface cicatricial lines are observed, most distinct about the bases of the growths.

Remarks.—In connection with this specimen I would like to call the attention of the members to a minute description of a similar specimen by Dr. Woodward. His article may be found in the *American Journal of Medical Science* for January 1881, and is entitled pseudo-polypi of the colon; an anomalous result of follicular ulceration. According to the writer, the origin and development of these polypi is as follows: 1. A granulating ulcerated surface of the intestine. 2. Numerous islets of mucous membrane on this surface. 3. "The formation of cicatricial contraction commenced in the infiltrated sub-mucosa constricting the margins of the islets of mucous membrane, which were further transformed by hyperplastic inflammatory processes, until ultimately they acquired the form of pedunculated excrescences, and projected into the lumen of the intestine like so many little polypi," being pushed out by the contraction of the connective tissue. Although the surface of the mucous membrane appeared to the naked eye healthy, with the microscope it showed it was sub-mucous connective tissue infiltrated with lymphoid elements. As pseudo-polypus was composed of a central portion of connective tissue, and a peripheral portion of diseased mucous membrane, the former continuous with the sub-mucous layer, the latter limited to the surface of the growth. The histological changes in the mucous and sub-mucous layers resembled those of chronic inflammation. The remainder of the bowel showed follicular ulceration. I am unable to say

what the condition of other parts of the bowel in the specimen exhibited was.

Case 2. For this specimen I am indebted to Dr. Gittings, of West Phila., for whom I made the autopsy. It was removed from a well-known druggist of this city, who had been a sufferer from chronic dysentery for some time. The bowel affection was especially severe during the past summer. He had been ill of an acute exacerbation for about a week when Dr. Gittings was asked to see him. The symptoms were of an acute dysentery, but not alarming. The effect of the habit of using chloroform, chloral and alcoholics to excess, which habit he continued during his illness, complicated the clinical features. About the tenth day of his illness the typhoid state suddenly developed and he died in coma two days thereafter. His temperature never was higher than 102°, tormina and tenesmus was marked, bloody and mucous discharges were excessive.

Autopsy 18 hours after death. Rigor mortis marked. Body well nourished. On section the abdominal walls were loaded with fat, and large deposits of this tissues were found in the great and lesser omentum, the meso-colon and the epiploic. The mesenteric and lumbar lymphatic glands were not enlarged. The cecum was surrounded by the lymph, the appendix bound down by adhesions and thickened. The colon was dilated, the transverse and descending colon contracted; the walls of the entire colon were thickened. On opening the large intestine it was found to be extensively ulcerated. The mucous membrane and the ulcers were strikingly anæmic and of a pale cream color; there were no points of hemorrhage. The walls were thickened; the mucous membrane swollen; the ulcers were more numerous and larger in size at the cecum. The smaller ulcers were the size of a dime; some of the larger extended around the gut, and were one-half inch to an inch wide. The edges of the ulcers were regular, beveled and thickened, the floor rather clean; the deepest did not extend beyond the muscular coat, the more superficial only included the mucous membrane. The larger ulcers were on the top of the folds of the intestines. A tenacious thick mucus covered alike the ulcers and the adjacent structures.

Condition of other organs.—Liver enlarged and fatty. Kidney markedly cirrhotic. Spleen normal. Heart slightly hypertrophied. Microscopical examination revealed the changes in the intestine of chronic inflammation, and that the ulceration was of a simple nature and not due to tubercle.

A Case of Carcinomatous Sarcoma of the Left Testicle.

Presented by Dr. W. G. MacConnell.

This specimen was removed from a young man by Prof. Brinton, at the surgical clinic of the Jefferson Medical College Hospital, on Wednesday, November 7, 1883.

History.—Jacob A., æt. 26 years, a clerk; about eighteen months ago, struck his testicle, in mounting his horse, on the pommel of the saddle, from the pain of which he fainted. No inflammatory enlargement, however, of the organ ensued. Last May he noticed that the left testicle had begun to enlarge, which continuously in

creased in size until it had attained the present volume. There was a sense of heaviness in the tumor, but no pain was experienced until about two weeks prior to its removal, when he noticed a periodical pain of a burning nature, which, with the increasing size of the organ, caused him to apply for relief. It weighs about 8 ounces, and measures in its long diameter $4\frac{1}{2}$ inches, transversely $3\frac{1}{4}$ inches, and about $2\frac{1}{4}$ inches in thickness. No lymphatic involvement was present, nor was the cord involved; the veins of the scrotum were enlarged and prominent. The tunica vaginalis testis is slightly thickened, and very opaque. The tunica albuginea is also thickened, and a slight remnant of the epididymis exists in the form of a small-fibrous lump. Its shape is somewhat that of a kidney, and upon section showed a moderately firm, buffy-colored tissue. It did not cry under the knife. In color and consistence it resembled the soft fibromata; distinct remains of the fibrous septa are to be seen; there are no cystic changes or any chondroid tissue present. Its microscopical appearance and consistence suggested a spindle-celled sarcoma, and as such, upon section, I diagnosed it. Microscopically, at a first examination, from the great ecstasis of the epithelium present, I was inclined to regard it as a pure medullary carcinoma; but after a careful study of several sections, I am inclined by reason of the juvenescence of the connective tissue, both round and spindle cells being present, to call it a sarcomatous sarcoma. There was no history of syphilis, scrofula, or tubercle, nor had any member of his family ever labored under any form of tumor.

Dr. Nancrede called attention to the fact that modern microscopic study has shown that carcinoma of the testicle is a rare disease, most malignant tumors of that organ being really sarcomata. In this connection it is of much practical interest to note that the system becomes infected at a relatively late period of the disease, so that when a sarcomatous testicle is removed at an early stage of the disease, prolonged immunity, if not actual cure, resulted. The inguinal and retro-peritoneal glands were those usually affected, their enlargement, by pressure, pain, etc., being the ultimate cause of death. Even more distant lymphatic glands are in rare cases involved.

Dr. Formad agreed with Dr. Nancrede. Some years back he had paid special attention to the study of malignant growths of the testicle and ovary. Of the former, he had examined thirty cases, all of which were sarcomata. He did not believe in the existence of such a growth as true carcinoma of either the testicle, ovary, or kidney. The so-called carcinoma of those organs exhibit cells of a *connective-tissue type* rather than of an epithelial. Dr. Formad considered, with many other observers, that the so-called epithelial cells of kidney, testicle, and ovary are really *endothelial*, and gave reasons in support of this view. He further said that there is a variety of endothelial carcinoma occurring in the breast which is that usually described as alveolar sarcoma. Here the endothelial cells of the lymph-spaces proliferate, but the glandular elements of the mamma do not participate. It is doubtless from the examination of such tumors that Virchow, and Cornil, and Ranvier, have gained the erroneous idea that true

carcinoma takes its origin from connective tissue. The speaker would suggest the term "*endothelial carcinoma*" for such tumors instead of "alveolar sarcoma."

Dr. Davis could not think that Dr. Formad was correct in absolutely denying the existence of carcinoma of the testicle, ovary, and kidney.

Dr. MacConnell agreed with Dr. Nancrede as to the relative frequency of sarcoma of the testis, having examined a large number of such specimens. He could support the views of Dr. Formad as to the growths of the testicle originating largely in proliferation of the endothelia of the lymph-spaces and tracts.

Sarcoma of the Breast.

Presented by Dr. G. E. De Schweinitz.

Some weeks ago I had the pleasure, through the kindness of Dr. Ashhurst, of exhibiting a specimen of cysto-sarcoma of the female breast, and to-night I am once more indebted to him for the privilege of showing this tumor, also a cysto-sarcoma, but differing in type from the previous growth. It is another instance of the truth of the remark, so justly made by Rindfleisch, that "the expression cysto-sarcoma is by no means to be conceived as the designation of a definite, perhaps round-celled, sarcoma with cysts, but it only tells us that a new formation with the textural character of histioid tumors has attacked the mamma and dilated its preformed cavities. This growth was removed from the person of a lady of middle age, married, but childless. She assigns no cause for its appearance. The growth of the tumor has been slow, it having originally been noticed six years prior to the date of operation. The weight of the mass immediately after removal was three pounds and one ounce. On palpation there was a distinct sense of fluctuation; the skin over the tumor was discolored, but not adherent. On section the growth is seen to be composed of two parts, the one about the size of a closed fist, and the other somewhat smaller. The section evacuated a quantity of bloody, mucous-like fluid. The centre of each mass is seen to be cystic, or rather the masses are the papillary and irregular excrescences which have protruded into the dilated ducts. The growth is composed of numbers of variously-shaped nodules, whitish or yellowish white in color, but in some spots semi-translucent, and resembling somewhat colloid material. The microscopic examination of various portions shows a similar result, differing only in degree—large round-celled sarcoma tissue, and some spindle cells, generally diffuse, but in places tending to alveolar arrangement; here and there round, stellate and spindle cells branched and anastomosing (mucoid tissue); numerous blood-vessels, usually wall-less, or mere channels passing through the tissue. In many places the sections show the enlarged ducts, cut transversely, and lined with a single layer of columnar epithelium. Surrounding them is a dense matrix of connective tissue. It may not be uninteresting to state that the specimen has been preserved in a solution of hydrate of chloral (gr. xx., f $\frac{3}{4}$ j.), after the manner originally recommended by Dr. W. W. Keen, with what success the beautifully fresh and natural appearance of the growth plainly attests.

C. B. NANCREDE, Recorder.

EDITORIAL DEPARTMENT.

PERISCOPE.

Congenital Encephalitis.

The *Med. Times and Gaz.*, November 17, 1883, says:

An address on the subject of Congenital Encephalitis was delivered before a recent meeting of the Berliner Medicinische Gesellschaft by Prof. Rudolf Virchow, in which, recalling certain observations made by himself in the year 1865, he undertook to prove the inflammatory nature of certain changes in the brains of newly-born children, which some subsequent observers have regarded as physiological, and not abnormal. These changes, as he first observed them, consisted in the appearance of very numerous granular cells and granular globules, scattered chiefly in the white substance of the cerebral hemispheres. For the most part in very regular order throughout the whole area, while there was absolutely no change in the appearance of the grey matter. These observations were published eighteen-years ago, and it was then suggested that the changes were inflammatory; they have been again and again observed by other pathologists, and their frequent occurrence has led to the opinion that they are normally produced in the development of the brain. The extent to which such changes are congenital, however, cannot be proved in every case. In the brain of a child born dead, no doubt can exist; but in the case of a child which may have lived only a few hours, doubts may very reasonably be entertained. With each day of life it becomes more and more uncertain how far the appearances may be regarded as congenital.

The elements thus found in the brain are quite unmistakable granular cells and granular globules. As long ago as 1846, Prof. Virchow drew out a classification of the various modes in which fatty changes may occur in cells. Three different forms were distinguished, and they have not since been added to. In the first the fat within the cell belongs properly to the character of the tissue of which it forms a part; in the second the appearance of fat-granules is always the forerunner of disintegration of the cell in which it appears; in the third the appearance of the fat is only transitory. From the form of fatty change alone, however, it cannot be determined whether the change is to be classed as physiological or pathological: other considerations must determine that point.

To which of these three classes of fatty change must the appearance in the newly-born brain be attributed? To assume the first would be to allow the possibility of the occurrence of normal fatty tissue in the brain. Putting this aside, we must look either to the possibility of transitory absorption of fatty matter, or to a process of fatty degeneration. As against the former must be placed the truly fatty nature of the change—the absorbed particles are not myelin—and the absence of any disintegrating points in the affected

brains from which granular material could be taken up.

"I am convinced," says Prof. Virchow, "that this condition is a fatty metamorphosis in the strictest sense of the word, and for this reason: because all the transition stages, from the intact cell to the granular, from the granular to the globular, and at length to the simple masses of fat, are here present, just as we recognize them when occurring in the fatty metamorphosis of other organs. Besides the diffuse form, however, of which I have spoken, there is a second form appearing in a more or less nodular manner."

The latter is easily to be seen with the naked eye. "One notices in the midst of the white matter dull spots, which become more and more opaque, and after a time take on a faint yellowish-white appearance, and finally commence to soften at individual points, and to become true centres of disintegration. These centres are distinguished by a peculiar change of the axis-cylinder which they present, in addition to the excessive formation of granular cells and globules, which consists in a varicose swelling and subsequent falling apart of the divisions thus formed, so that one can demonstrate long, varicose, often spindle-shaped bodies between the fatty particles. If one now compares a sufficient number of these two categories of cases, the diffuse and the circumscribed, it becomes apparent that there is by no means an essential difference between them, but that the circumscribed form represents an exaggerated condition of the same process which is found diffused.

In order to determine the relative frequency of the occurrence of these changes—the one point upon which the theory of their physiological nature has been based—Prof. Virchow has lately instituted a series of investigations of the brains of still-born and newly-born children, extending to 44 cases in all. Of these 22 were born dead, 5 died during birth, 17 lived for various periods up to five weeks; but of these most died during the first day. Twenty-seven were congenital in the strictest sense, and of these only 11 showed the appearances described, abundantly in 8 cases, and sparingly in 3. Of 9 immature embryos examined, only 3 failed to show the changes; of those born dead at full term, 9 showed no changes, and in only 3 were they present. From these purely objective investigations, it follows that the appearances in the brain do not occur with such constancy as to warrant the belief that they can be of normal origin. Turning, now, to the examination of those cases in which death took place at varying periods after birth, only 3 cases out of 17 were found to be free from the condition. These three cases with normal brains were each distinguished by all the signs of inherent weakness; whilst at least eight of those with affected brains showed no predominant symptoms of feebleness whatever. From a careful consideration of all the cases, it appears clear that there is no ground for the supposition that this change in

the brain is but a part of a general disturbance of nutrition.

"I should certainly be the last to deny that such a fatty metamorphosis *may* be the result of a bad state of nutrition; and if such a connection could be established I should have nothing to urge against it in this case; but, nevertheless, I must always consider that it would be a disastrous state of affairs if general atrophy or want of proper nutrition were always to lead to this condition of brain. In all those cases in which, as far as I am aware, fat occurs as a consequence of bad conditions of nutrition, it appears to be universally attracted to the walls of the vessels, in which at any period of age, as a result of impaired nutrition, such changes may occur in a very marked manner even to the smallest capillaries." The granular cells previously described, however, could be clearly demonstrated to have no connection with vessels.

A challenge is thrown down to any workers in the same field of investigation to prove the association of these fatty metamorphoses with general conditions of impaired nutrition. Regarding these changes as indicative of encephalitis due to a condition of irritation, Prof. Virchow directs attention to an analogous change which is recognized in the tissues of the optic nerve in retinitis, in which granular globules appear in the interstitial tissue, and in which a varicose and gangliform alteration of the nerve-fibres is induced. Although the process in the brain cannot be said to be an inflammation in the strictest sense of the word, it is, nevertheless, an irritative process—*i. e.*, a process in which the fatty metamorphosis is not immediately apparent, but in which a definite series of irritative changes lead to that result.

The Administration of Salicylic Acid.

In *Squibb's Ephemeris* for November, we find the following:

The apyretic effect of salicylic acid is one of the most remarkable and important therapeutic discoveries of the age, and its control over all such conditions as are generally met with in acute and subacute rheumatism is almost complete. Its applications, therefore, in medicine are very numerous and very important.

In its internal use the points most necessary to be borne in mind are the disturbing effects of very large doses, and the rapidity with which it is eliminated. It should, therefore, be given in full doses at first until the impression is made, and then in moderate or small doses frequently repeated.

It is best given in wafers or cachets, and it should not be packed into capsules. Two or three doses of fifteen to twenty grains with two or three hours' intervals will usually produce its characteristic beneficial effects. Then ten grains every two hours, with intervals gradually increasing to three and four hours, serves to keep up the effects with the smallest risk of such disturbance as will require it to be suspended when most needed.

Of late it has been more rarely used, the salicylate of sodium having taken its place with the same effect, and with some advantages.

It is a curious and very interesting and important circumstance, that full doses of salicylic acid

or salicylates do not interfere with the digestive functions of the stomach, and yet a very small quantity will prevent the action of pepsin. At least this statement is made on what appears to be good authority.

An ordinary cold saturated solution contains somewhere about one part in three hundred; and such a solution is very convenient indeed, as a vehicle for solutions of alkaloids for hypodermic use. If a drachm of the acid be added to a pint of water, and the mixture be well shaken, such a solution, with some undissolved acid at the bottom of the bottle, will be the result. Then if this be used entire, or diluted with an equal volume of water, for making hypodermic solutions, such solutions will remain free from growths of all kinds for an indefinite length of time, and will not be more irritant than if made from water alone.

Absorption of Fat in Adults and Children in Fever and Apyrexia.

The *London Med. Record*, December 15, 1883, says:

Following a suggestion by Professor V. A. Manassein, Dr. V. E. Tchernoff (*St. Petersburg Inaugural Dissertation*, 1883,) investigated the assimilation of fat by adult subjects and children suffering from febrile diseases. The observations were conducted on twenty-two patients, nineteen of them being between 7 and 42 years of age, the remaining three under a year. Seven of the patients suffered from enteric fever, two from recurrent fever, four from typhus, two from erysipelas, one from malarial fever, two from croupous pneumonia, and one from varioloid. Of the infants, one had fever from vaccination, one suffered from scarlatina, and one from catarrhal pneumonia. The patients (those between 7 and 42 years of age) received milk, in which the proportion of fat had been previously ascertained, and bread; their feces, made from the beginning of an experiment, were collected and analyzed. The author sums up his results as follows:

1. A healthy subject assimilates about 90 to 94 or 95 per cent. of fat of the food given, provided it be present in a form suitable for the action of bile and pancreatic juice.

2. A subject suffering from a febrile disease, as a rule, assimilates lesser quantities of fat than the same subject in a healthy state, the difference being on an average 7.2 per cent.

3. The single deviation from this rule is given in enteric fever. When suffering from the latter, the patient absorbs more of fat than when he is convalescent, or quite well. This is especially true in regard to severe forms of typhoid.

According to the author, the fact of fat being better assimilated by typhoid patients finds its explanation in the presence of great numbers of leucocytes in the intestines in cases of enteric fever. As a recent work of Professor F. N. Zawaykin shows, leucocytes are "true absorbers and distributors of fat."

4. The quantity of absorbed fat, and the percentage proportion of fat in feces, are influenced by the quantity of fat in the food daily taken, by the individuality of the patient examined, by his general state at the time of examination, and,

possibly, by the admixture of carbohydrates and albuminoid matters.

5. There exists no difference between adults and children in regard to all the propositions stated above.

6. Febrile patients, though their faculty of the absorption of fat is diminished, still assimilate fat in considerable quantities (from 80 to 90 per cent.). Therefore, any fears entertained against the administration of fat to febrile patients are groundless. Any avoidance of fat in febrile diet would be unjustified: fat is as necessary for the diseased as it is for the healthy.

The Exact Value of the Electrolytic Method.

When any suggested remedy has not equalled its promises it is well that prominence should be given to the fact, that too much confidence may not be reposed in it. In the *New England Medical Monthly*, December, 1883, Dr. A. D. Rockwell says that electro-surgery, and especially electrolysis, has not equalled the brilliancy of its promise, and he thus concludes his article:

Without occupying time by the recital of illustrative cases, I would offer the following summary as indicating as nearly as possible, the exact value of the electrolytic method in surgical diseases:

1. The success to be met with in the treatment of malignant growths in general is but trifling. The size is sometimes reduced, and the pain is almost always greatly alleviated. In the class of cases, however, termed epithelioma, when the disease does not extensively involve the subjacent tissues, and where it is easily reached, it is probable that in the majority of cases the very best results will follow thorough and persistent treatment.

2. Fibroids being dense and comparatively dry, do not readily shrink under electrolysis, and it is seldom that we can accomplish more than some slight diminution in bulk. The results following this limited influence, however, are especially valuable in the case of uterine fibroids of an intramural character where the knife cannot be used. The pressure upon the bladder and rectum is in these cases greatly lessened, or entirely dissipated, and the relief that follows is immense.

3. It is in erectile and small cystic tumors that electrolysis is most effective. In these conditions it is indeed a specific. The cure that follows is complete, and with proper care scars can be avoided.

4. The ordinary form of goitre acts somewhat capriciously under electrolytic treatment. Goitres that are small and soft may not only be treated effectually by the introduction of needles, but external applications alone will sometimes cause them to entirely disappear. Even when they are quite large, if their density is not too great, a perfect cure may follow. Where they do not entirely disappear, they may almost invariably be reduced in size, affording in many cases marked relief from the pressure that is so distressing.

5. By this method hairs may be permanently removed. The negative pole and a weak current are to be used.

6. In many cases of urethral stricture permanent relief is afforded. A more extended experience, however, is necessary to establish its exact value.

Sudden Death Due to Hemorrhage from Hepatic Vein.

Dr. Alfred F. Holt reports a case in the *Boston Med. and Surg. Jour.*, December 20, 1883, which was verified by autopsy. The case he describes as follows:

J. C., an Englishman, fifty-six years of age, large and strongly built, though slightly hunch-backed, died May 15, 1883. For the last six or seven years of his life he had been engaged in a small kindling-wood trade, doing some of the manual labor required by such a business himself. For the ten years before this time he had been a police officer.

Ten or twelve years before his death he began to have severe attacks of colic. These continued to occur at irregular intervals during his life, and for the last six or seven years he was never quite well, although able most of the time to attend to his business. During these years he had consulted a large number of physicians. Most of these pronounced his trouble gall-stones, but some of them dyspepsia, and still others some obscure disease of the liver.

Seven days before his death, while in Boston attending to some business, he was suddenly prostrated with a very severe attack of pain in the region of the stomach, nausea, and faintness. He was taken to his home in Cambridge in a carriage, and his physician, Dr. Dow, was immediately summoned, who found him suffering from severe pain, vomiting at short intervals, pale, and faint. The pain and faintness continued until evening, he having been taken sick about noon, when the doctor was hastily called again. He found him vomiting blood in the form of very large dark clots. This continued at short intervals for about one hour, when it ceased. A little over three pints of blood was vomited at this time. The pain and faintness continued for three days. Although these symptoms were somewhat relieved by stimulants and opiates, at the end of this time he was again attacked with the vomiting of blood, as before, in the form of very large black clots. This continued at short intervals until nearly two quarts had been ejected, when it suddenly ceased; and after this he was very weak, faint, and nearly pulseless. The pain continued a few hours after this vomiting, when it ceased. Although his mind was clear, he did not rally, but gradually sank, and died forty-eight hours later, or a little less than seven days from the commencement of the sickness. No blood was at any time passed by the rectum.

High Amputations for Senile Gangrene.

Before the Royal Med. and Chirurg. Society (*Med. Times and Gaz.*, December 15, 1883), Mr. Hutchinson read a paper on the above subject, which began by the statement that the author's chief object was to urge the safety and expediency of amputating in senile gangrene if the operation were done at a good distance from the disease. In the common form of gangrene of the toes and foot, the lower third of the thigh was the part suggested, and in rare cases in which the hand is affected, the middle of the upper arm. After remarking on the fact that amputations had hitherto generally proved disappointing, owing to

return of the disease, the author urged that this was from their usually having been done too low down. The calcification of the arteries, upon which in the main the disease depended, was usually greatest near the periphery, and hence the difficulty as to supply of blood for the nutrition of the flaps. This source of danger was not encountered if the amputation were done sufficiently high. In a series of cases in very old patients, the author had not encountered the recurrence of gangrene excepting in one. In three the stump had healed well. In a fourth, in which the patient, although not old, was prematurely senile, and the calcification of the arteries extreme, the recovery had also been excellent. In this instance the femoral artery was so rigid that it stuck out from the face of the stump like a small bone. One of the patients in whom the stump had healed without a drawback was seventy years old. In two of the cases the other foot had subsequently been threatened with gangrene. As to the time to be selected, the author thought that as soon as the patient was so ill as to be confined to bed, and the disease well established, it was better to do the operation. Spontaneous cure was, he urged, very exceptional, and a great majority of such cases ended in death after a long period of much suffering. The thinner the patient the less was the probable risk of the amputation. In a few cases in which the thigh was exceptionally fat and the tissue flabby, it might be wise to hesitate as to recommending it. In all his cases Lister's precautions had been carefully used, and in two or three the patient had never experienced the slightest pain from the day of the operation.

The Treatment of Pelvic Cellulitis following Parturition.

Dr. W. M. Graily Hewitt thus concludes an article in the *Med. Press*, November 21, 1883:

A few words with respect to the treatment: A remarkable feature in these cases is their tendency to chronicity. They are always tedious and difficult to cure, and the cure depends more on attention to diet than on any other element of the treatment. Rest, of course, is an essential; but the nutrition requires careful consideration. With regard to the subject of food: Deficiency of food may predispose to cellulitis in a patient in whom other factors in its cause may be present; or it may render an already-existing case of cellulitis less amenable to treatment. In the case before us the quantity of food taken was perhaps only one-third of the total amount required by the healthy subject. This created a weakness which showed itself in various ways. Under these circumstances there is great indisposition to take food, and if only three stated meals a day are provided, a very small amount is taken; the patient becomes exhausted in the intervals, and when meal-time comes is not able to take nourishment. Hence the quantity taken is not enough to induce activity in the nutrition process, but only enough to keep up a condition of *statu quo*. To stimulate nutrition, articles capable of ready assimilation must be selected—Brand's essence, beef tea, milk, etc., with a fair amount of stimulant in the shape of brandy, and this must be given very frequently, every hour or so. Under this treatment

the appetite will rapidly improve, and in a week or so, in all probability, solid food will be taken with zest.

As subsidiary treatment, poultices may be applied to the abdomen to relieve pain and assist resolution, and if the latter is very severe a little opium is indicated. The bowels should be daily opened by the administration of a mild laxative. Some medicine, in the shape of dilute nitro-muriatic acid with a little tincture of orange, is often useful as a stomachic and tonic; and later on iron and quinine may be given with advantage.

Trichlorphenol in Syphilographic Practice.

The *London Med. Record*, December 15, 1883, says: The excellent results which had been obtained by Dr. Rubetz from the use of trichlorphenol in phagedænic chancres (see the *London Medical Record*, April, 1883, p. 132), induced Dr. S. P. Tomashevsky, of Prof. V. M. Tarnovsky's clinic, St. Petersburg (*Vratch*, 1883, Nos. 18, 19, 21, and 22), to try the remedy in nine cases of soft chancres of the glans and prepuce, in seven of ulcerated chancreous buboes, and in several cases of primary syphilitic ulcers, deep syphilitic ethymata, and gummy ulcers of the skin and subcutaneous cellular tissue. He used from one to two and a-half per cent. solution of trichlorphenol (R trichlorphenoli 3j to 3ij ss., spiritus vini q.s. ad solut., glycerini puri lb. j), which was applied to the diseased surface three times daily. Dr. Tomashevsky's results strongly differed from those of Dr. Rubetz; in fact, they were so unsatisfactory as to have compelled the author to give up any further trial of treatment by trichlorphenol. In eleven of fifteen cases of soft chancres and buboes, even two or four weeks' application of the lotion did not check the ulcerative process; the ulcers finally rapidly healed under iodoform. Of the remaining five cases, one (which, possibly, represented only an instance of ulcerated herpes progenitalis) was cured in eleven days; in other four cases the cure followed in nineteen days. In almost all the cases, the use of trichlorphenol produced inflammation of the periphery of ulcers, which induced him to lessen the strength of the solution. As artificial or accidental inoculations showed, the discharge of chancreous ulcers dressed with trichlorphenol did not lose its virulence during a considerable period after the commencement of the application. Of the syphilitic cases, only one—that of an obstinate deep ethyma of the leg—was successful, the ulcer rapidly healing under a two per cent. solution of the drug. In the remaining syphilitic patients, trichlorphenol displayed too strong irritating local action to permit any prolonged experimentation.

Tuberculosis in Childhood.

The *London Med. Record*, December 15, 1883, says an interesting discussion on this subject occupied one of the sittings of the Congress of German Physicians and Naturalists held recently at Freiburg (*Wiener Allgem. Med. Zeitung*, Nos. 39-40, 1883.) The relative frequency of the disease in new-born children, its development in early childhood, and the dangers of infection to which children become exposed, were each in

turn considered. Prof. Demme, of Berne, gave as the result of his investigations the following facts with respect to the locality of the attack in congenital tubercular disease—viscera, 71.8 per cent.; joints and bones, 69.6; peripheral lymph glands, 65.4. The disposition to the development of tubercle is much increased after attacks of measles or prolonged whooping-cough. While maintaining that the inhalation of tubercular poison is more to be feared than its ingestion, he showed by his own and foreign observations the relative frequency of tubercular poisoning by un-boiled milk, derived from animals affected with bovine tuberculosis. Professor Rauchfuss, of St. Petersburg, contributed a valuable summary from the pathological records of the Foundling Hospital in St. Petersburg, to show the relative frequency with which individual organs become attacked. His figures show that the lungs and bronchial glands are affected in nine-tenths of the cases; the liver, spleen, intestines, kidneys, pia mater, pericardium, and peritoneum follow in that order. A similar summary, derived from the large Foundling Hospital in Moscow, and arranged by Professor Klein, differs in small points only. The lungs and bronchial glands again head the list, which gives the liver, spleen, kidneys, choroid, intestine, pia mater, as next in order of frequency.

Fractures of the Patella.

Dr. William MacEwen contributes a paper on this subject to the *Lancet*, November 17, 1883, from which we take the following:

1. The chief cause of non-osseous union of the patella in cases of transverse fractures is the interposition of fibrous and aponeurotic structures between the fractured surfaces. 2. If osseous union be desired in transverse fractures of the patella, it is requisite, in the first instance, to elevate all the tissues which lie over the fractured surfaces, and which prevent them from coming into intimate contact. 3. From the ease with which the two fragments, in many instances, may be maintained in position, it is probable that osseous union could be obtained without suturing, provided these soft tissues were first elevated. Practically, however, suturing the patella ought to be adopted, as it is the easiest and surest way of securing accurate apposition, and adds no risk to the operation. The operation of elevating the soft structures between the fragments and of suturing the bone ought to be undertaken within the first forty-eight hours from the time of injury. 5. In order to lengthen a muscle, a series of V-shaped incisions made into its substance in a transverse row will effect the purpose, while not diminishing its strength as transverse incisions do.

Sulphate of Soda in Carbolic Acid Poisoning.

Dr. John Reid reports this case in the *Brit. Med. Jour.*, November 17, 1883:

Mrs. W., aged 35, drank, with suicidal intention, somewhat less than four fluid ounces of crude carbolic acid. When seen half an hour afterwards, she was comatose, the pupils were contracted, and cornea-reflex was absent; the pulse at the wrist could with difficulty be felt; the first

sound of the heart was almost inaudible; whitening of the lips and mouth were not present, yet the breath smelt of carbolic acid. The pump was not used; but about an hour after taking the poison, four drachms of sulphate of soda dissolved in five ounces of water were injected into the stomach through a catheter; two hours later, three-quarters of an ounce of the salt in five ounces of water. After each injection, the patient appeared to be somewhat relieved in breathing; four hours after this, or about seven after taking the poison, cornea-reflex had returned, the patient groaned somewhat, and the pulse had slightly improved. Three-quarters of an ounce of sulphate of soda in five ounces of water was now injected, after which the patient appeared to be easier. She died in about forty minutes.

Ether was injected at the end of the first, third, and fifth hours, and probably the result would have been different had an injection been given at 2 p. m., after which I had to leave somewhat suddenly. The patient had been ailing for some time. Sulphate of soda has succeeded in the case of animals, and if this drug has not been used in man, the case may be of interest.

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—We have received the report of the ninth annual meeting of the American Neurological Association, held in New York last June. It contains some interesting papers that will prove valuable reading to the general practitioner as well as the specialist.

—The Introductory Address to the Medical Class at Dartmouth College, by Dr. Louis Elsberg, has in it a good deal of fresh thought, and some quaint original talk about the relations of health and disease.

—Of interest to those pursuing sanitary studies is the little pamphlet, entitled "The Geology and Topography of Iowa in a sanitary point of view." It was prepared by Dr. P. J. Farnsworth for the Iowa State Board of Health.

BOOK NOTICES.

The Dissector's Manual. By W. Bruce Clarke, M. A., etc., and Charles B. Lockwood, F. R. C. S. H. C. Lea's Son & Co. 12mo., pp. 391.

This is another of the English manuals for students, a series which we have taken occasion previously to note as one of the most satisfactory which we have yet met with. The present number has a moderate show of engravings, and the descriptions are full enough for the purpose in view. It will be found a useful little volume.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

PUERPERAL FEVER.

The difference between the practice of the ordinary physician and of the fashionable specialist was never more perfectly illustrated than by a comparison of the *usual* treatment of puerperal fever or puerperal septicæmia and that recommended by Dr. T. Gaillard Thomas in his admirable address published in the *N. Y. Med. Jour.*, December 15. Dr. Thomas is a man of immense experience, and his views are invaluable; every word he utters is a pearl of wisdom, and is pregnant with great good; but a careful and thorough carrying out of his minute directions would be simply an impossibility to any one not abundantly blessed with wealth. Still, since half a loaf is better than none, we will give an editorial summary of his views, so that they can be carried out as far as possible.

In the first place Dr. Thomas regards what we are wont to call puerperal fever, as a septicæmia, produced by the entrance of septic germs into the system, through the lacerations of vulva, vagina or cervix caused by the passage of the child at the time of parturition, or through the open sinuses at the point of detachment of the placenta. Therefore his whole principle of treatment is really directed towards combatting this septic state.

He enunciates a series of prophylactic measures, which may be summed up in the one word "*disinfection*." Every article in the proposed lying-in room, walls, floor, furniture, should be thoroughly washed with a ten per cent. carbolic acid, or a 1 to 1,000 solution of mercuric bichloride.

The physician, the nurse, every one and everything about the lying-in woman, should be thoroughly disinfected. A potent factor for the introduction of disease germs is the catheter; this should be thoroughly disinfected before use, and Dr. Thomas says: "It is a very common and very bad habit for nurses to own silver catheters, which they carry about with them from case to case of midwifery."

After the completion of labor, the physician should carefully examine the vulva. Should he

find the perineum lacerated, it should be closed at once by suture, to shut up this avenue to septic absorption, and, should slight solutions of continuity be found in the labia or the vulvar extremity of the vagina, these should be dried by pressure of a linen cloth, touched with equal parts of sol. ferri persulph. and carbolic acid, again dried thoroughly by pressure with the cloth, and then painted over with gutta-percha collodion. If this be thoroughly done, absorption will be prevented at these points for at least three or four days, when the application may be repeated.

"In six or eight hours after the labor, when the patient has rested, the vagina should be syringed out with an antiseptic solution, and a suppository of cocoa butter, containing from three to five grains of iodoform, should be placed within it, under the os uteri. A syringe with intermittent jet should be used, which will wash away with gentle force all blood-clots, and reliance should not be placed upon the feeble drip of the fountain syringe, the advantages of which are, I think, entirely theoretical.

"These vaginal injections and suppositories should, in cases of normal labor, be repeated every eight hours; in cases of difficult or instrumental labors, twice as often; and they should be kept up for at least ten days, the nurse observing to the last the precaution already mentioned of washing her hands before every approach to the genital tract of the patient."

The principles for treatment are very similar to those for prevention. He would rely, principally, upon antiseptic injections.

"The physician must now decide whether, in his opinion, the septic disease which is developing has originated in the wounds situated between the os internum uteri and the vulva, or in the endometrium, above the former point. If he decide in favor of the former view, he should persist, for a time longer, in the more thorough use of vaginal injections; if of the latter, intra-uterine injections should be at once resorted to. Usually the question has to be decided by the efficacy or ineffacy of frequent germicide vaginal injections in bringing down the temperature and controlling other grave symptoms. Should a failure of these seem to prove that the origin of the disease is higher up the genital tract, more decided and radical measures must be taken."

"That the use of antiseptic uterine injections

after parturition is attended by danger, is beyond question. The greatest hazard attending this plan is the entrance of air into the uterine cavity; the next, the production of hemorrhage by detaching some of the thrombi which fill the mouths of the uterine sinuses; the third, the danger of forcing the fluid used as an antiseptic directly into the general circulation, through the introduction of the tube into the mouth of a sinus; the fourth, the creation of convulsions, violent pain, or nervous prostration, by a sudden and baneful influence upon the nervous system; and the fifth, the passage of the tube into a Fallopian canal, and the injection of fluid directly into the peritoneal cavity, as in a case reported by Dr. W. Gill Wylie in an interesting paper in the *New York Medical Journal* for June 23, 1883, p. 679.

"All these dangers may be, to a great extent, avoided by care as to details: by using a large injecting tube which cannot enter an open-mouthed sinus; by using water warmed to 105°; by injecting the fluid through the tube so as to exclude air, before passing this up to the os uteri; by using only a moderate degree of force in throwing the jet against the uterine walls; and by proceeding with the whole affair gently, cautiously, slowly, and intelligently.

"The tube should never be allowed to fill the os uteri completely, so as to prevent the escape of the injected fluid. Should the cervical canal be so narrow as to hug the tube closely, it should be dilated by dilators of hard rubber, by the fingers, or by Barnes's bags, before the injection is practiced.

"A solution of the persulphate of iron should always be at hand in case of sudden hemorrhage from displacement of a thrombus. Should this accident occur, ergot should be immediately given hypodermically, the iron solution be at once added to the antiseptic solution and allowed to pass into the uterus, and pressure be made upon the fundus so as to stimulate the contraction of uterine fibre to accomplish closure of the open sinuses in that way."

In addition to the injections, Dr. Thomas would use quinine or salicylate of sodium to control the tendency to chill and pyrexia, and would confine the patient to a liquid diet, chiefly milk.

It will be seen that his whole treatment is essentially antiseptic, and that the agency he chiefly relies upon is corrosive sublimate. Dr. Koch, of Berlin, has recently demonstrated that mercuric bichloride possesses antiseptic properties, probably

superior to those of any other article in use, and its merits are now being very extensively tested.

While it would be impossible to strictly carry out Dr. Thomas' suggestions, save in the higher and fashionable walks of life, wherein money is no consideration and every possible requirement can be had, and also while we do not believe that so much trouble is called for in the majority of cases, and particularly among those in rural practice, yet we must commend in the highest terms the antiseptic doctrines inculcated.

Cleanliness, natural and antiseptic, of patient and attendants, are the two cardinal points in the prevention and cure of puerperal fever.

CRANIOTOMY—IS IT NECESSARILY FATAL?

Dr. W. D. Wilkes makes a novel suggestion in the *Med. Times and Gaz.*, November 17, 1883, which may or may not prove practicable, as future experience may demonstrate.

He calls attention to the fact that when the disproportion between the foetal head and the pelvic outlet is so great that natural delivery is impossible, and craniotomy must be resorted to, we are taught to pass the instrument well up to the base of the brain, that all life may be destroyed before delivery, and the mother and friends not shocked by the horrible spectacle of a living child with a mutilated head.

He then propounds the query, whether craniotomy is necessarily fatal either to life or to the subsequent intellectual well-being of the babe. Considering that it may not be, he suggests, that after explaining the situation to the friends, we should proceed to mutilate the head just as little as is absolutely necessary for delivery, and then subsequently treat the case as we would a similar case of head injury occurring under ordinary circumstances.

So great has been the progress of surgery of late years, and such wonderful cases have been reported of absolute recovery after the most grave and seemingly fatal injury to the skull and the brain, that we would not like to condemn this suggestion until it had been actually tried. Still, we cannot look upon it with much hope.

If we were the foetus, and had our way, we would prefer to be killed outright, for we fear the chances of restoration to usefulness would be very slight. A very unfavorable feature would be the almost absolute impossibility of securing rest and quiet, so essential to the successful treatment of head injuries; for it is not in the nature of an infant to keep quiet. It is true that this requisite might be procured artificially.

Again, the danger, we fear, of bringing into the world a human being, destined, on account of brain mutilation, to a life of idiocy, imbecility, or epilepsy, would deter most physicians from resorting to this suggestion.

Still the suggestion is worthy of remembrance, and when some suitable case presents itself, where the disproportion is so slight that but little mutilation would be required, and where *intelligent* friends and relatives, after a full explanation, are willing to assume all responsibility, it might be tried.

NATIONAL OR LOCAL EFFORT?

The direction in which efforts toward public sanitation should be chosen must depend in different governments on their varying political constituency. The plan best adapted for England or Germany will not suit in the United States; that successful in the republic of Switzerland will not be any the surer to prosper with us, because in many ways our domestic relations differ from those of that model little state.

The size of our country and the autonomy of our States are two factors in the problem of the first importance. There is a widespread dislike of control from a central bureau, and this is so true, that any attempt of a central office in Washington to interfere, or direct, or command the action of states or municipalities, will infallibly meet with opposition, and finally with rejection. Whether this is praiseworthy or whether it is not, need in no way come into the question. We speak of the fact as a fact, and it cannot be gainsaid.

The truth about it is well expressed in a passage in the last report of the United States Marine

Hospital Service. In the discussion of the sphere and the limits of national quarantine, Dr. Hamilton writes:

"In conclusion, it is proper to say that under existing law the duty of the government apparently ends with the maritime quarantine, and the question of local municipal sanitation is one which may not only with propriety be left to the States, but all existing law has heretofore done so, and that, however desirable it might be for the government to undertake the work of general sanitation, it is evident that the limits of such a work could not be foreseen at the present time. So intimately is this question connected with the local police and municipal government, that interference by Federal authority is not only unwarranted, but probably mischievous."

For this same reason the American Medical Association can never attain the strength and solidity of the British Association, and it will fail, as it has failed, if it goes out of its proper sphere as a scientific congress to attempt legislation by a central power. In the way of encouragement, unifying and aiding efforts, improving social relations, and stimulating legitimate ambitions, it will always have a fruitful field to cultivate. But when it attempts to act as an authoritative body, or to claim for itself a political power, it will excite opposition and pave the way for its own downfall.

The sentiment of individual, municipal and state independence is too strong in this country to be overcome by any centralized power, professional or political. May it long be so!

DRUG FARMS.

Some time since (see *REPORTER*, Vol. xlvii., p. 467,) we published an editorial on this subject, in which we expressed the opinion that some of our young men might, at least, manage to support themselves while waiting for practice by cultivating medicinal plants.

It affords us pleasure to note, from an article by J. W. Colcord, of Lynn, Mass., in the *Druggists' Circular and Chemical Gazette*, for December, 1883, that efforts are being made to interest the national government in this idea. From it we learn that at the last meeting of the American Pharmaceutical Association a resolution was adopted in-

structing the Committee on Legislation to ask Congress for an appropriation of \$25,000, to be expended in the introduction and cultivation of foreign medicinal plants. It seems to the writer that we have such a variety of climate within our borders that it would not be a difficult matter to find a location suitable for the cultivation of many of our valuable medicinal plants.

He tells us that the cinchona trees of India are now valued at \$5,000,000, and that this is the result of an outlay on the part of the Government of only \$500,000, less than fifteen years ago. He is now cultivating some seed of the *Rheum palmatum* from the Royal Botanical Gardens of St. Petersburg, and he kindly offers to distribute these seeds to any one interested in the matter who will send him a two-cent stamp for return postage.

We say again that this occupation would, if successful, enable some of our worthy but poor young country doctors to keep the wolf from the door while waiting for practice. To all so interested we would recommend a correspondence with Mr. Colcord.

RESPECT THE LAWS.

The public papers told us last week that a number of physicians in Lancaster, Pa., had received notice of suit for failing to comply with the municipal regulations about reporting births and deaths, and that one had been fined for not returning a case of epidemic disease (small-pox).

Such an incident as this should not have happened. Physicians who neglect the punctual and accurate observance of official regulations touching vital statistics and public hygiene—and surely we have few enough of them—are setting a bad example to the public, and acting in a manner not calculated to heighten respect for the profession.

How can we expect legislators to vote for health laws and health boards, when medical men disregard the slight local rules considered necessary for the hygiene of their own neighborhoods? Those assemblymen who are opposed to all such legislation will make this a weapon to use against

it; and thus such neglect not only is a bad example of disrespect to laws, and an injury to a neighborhood, but endangers the physical welfare of the Commonwealth.

The physician cannot be too punctilious in such matters.

NOTES AND COMMENTS.

Occlusion of Both Ureters—Death from Syncope.

A rare case is that reported by Dr. J. Vincent Bell in the *Lancet*, December 15, 1883. The patient, a corpulent but temperate man of 49, had occasionally passed small calculi, which he could trace, by his feelings, in their course along the ureters. Finally suppression of urine took place, and the patient was sure that calculi had become impacted in his ureters. The bladder was empty. Aperients, diaphoretics, and warm baths were ordered. This treatment was continued for two days, when he was found to be sweating, and there was a distinct urinous odor about the breath and skin, but he was almost free from pain. The patient felt that the calculus in the left ureter had nearly reached the bladder. He was hopeful and cheerful. He was sitting up talking business when he complained of feeling faint, was given some brandy, said, "I am going," and died instantly.

Both kidneys were enlarged to about double their normal size, congested and friable. There was a calculus of the size of a peach-stone in the infundibulum of the left kidney, and one about half that size in that of the right kidney; also two or three quite small calculi (scarcely as large as peas) in other parts of the kidneys. About one and a half ounces of urine escaped on section of the left kidney, rather less than one ounce from the right; the ureters were both blocked. On the right side a calculus was impacted about an inch above the bladder, whilst in the left ureter a less firmly impacted calculus had less than half an inch to travel, and seemed as if it might have escaped into the bladder within another day, if only that fatal syncope had been avoided.

The noticeable points in this case seem to be the rare coincidence of blocking of both ureters, the recognition by the patient of his own condition and the cause of it, and the death by fainting on what appeared to be the eve of recovery. The question whether any operative measures

should be adopted presented itself, but the difficulty and danger of trying to relieve the ureters with a collapsed bladder in a patient sliding into uræmia seemed to make the likelihood of a favorable result from such interference smaller than from a more expectant plan; and he thinks that the narrow escape from recovery which he apparently had, justified the decision.

Parasitic Worms.

At a recent meeting of the New Jersey Microscopical Society, Dr. Samuel Lockwood exhibited a full-grown dipterous larva taken from the inner ear of a man at Paterson, N. J. August 30. There was a perforation of the membrana tympani. The man had suffered seven days from its presence. The grub had entered the outer ear, but eluded an attempt to extract it by re-entering the drum. Appearing again in the external ear, it was extracted with forceps, and kept alive for several days. He referred to certain papers read to the society (one in 1880, and a sequel in 1881), in which he described specimens of dipterous larvæ passed by a man in large numbers, and which he determined to be larvæ of *Sarcophaga carnaria* and *Anthomyia canicularis*, which had come of eating tainted cold meat and cold boiled cabbage. Such cases are highly instructive.

Nervous Cough.

We are often called upon to relieve a disagreeable, dry, hacking cough, where we can find no evidence of lung trouble. In the *Med. Times and Gaz.*, Nov. 17, 1883, Dr. J. Mortimer Granville tells us that he considers this cough to be due to irritation of the recurrent laryngeal and pneumogastric nerves. It is important that it should be relieved, because the cardiac and gastric irritation which it produces, will cause such nutritive changes in the bronchial membrane and sub-mucous tissue, as to induce a low inflammatory action and the deposit of tuberculous lymph. To relieve it, he advises blistering over the pneumogastric nerve (along the whole anterior margin of the sterno-cleido-mastoid muscle will be near enough) with glacial acetic acid. This should be repeated every two weeks until the cough is relieved. Each side may be blistered alternately.

Arterio-venous Aneurism.

Dr. T. Pickering Pick reports a case in the *Med. Times and Gaz.*, December 15, 1883, the result of a gun-shot wound of the thigh, by which, most likely, the contiguous surfaces of the artery

and vein were bruised, but not actually cut through; adhesion then took place between these vessels, and subsequently the damaged spot gave way, and a direct communication was established between the two. Ligature of the artery, above and below the site of the aneurism, is so dangerous, that Dr. Pick thinks it is better to envelop the limb from the foot to the groin with a "Martin's elastic bandage," and if the patient can then attend to some light occupation, let well enough alone.

On the other hand, if the dilatation of the veins increases rapidly, so as to entirely incapacitate him from work, and especially if the patient's life is threatened from hemorrhage, he shall take the opinion of his colleagues as to the advisability of tying his artery above and below the point of communication.

A New Theory of the Etiology of Puerperal Eclampsia.

While so much doubt surrounds the causative agency of puerperal convulsions, it is permissible to theorize, hence we note that Dr. Henry Corby offers a new suggestion in the *Lancet*, November 17, 1883. He suggests two factors: First, retention of excrementitious urinary products in the blood, due to the pressure of the uterus on the large abdominal vessels, thus delaying the passage of the blood through the kidneys; and second, the irritation of the disproportionately large fœtus in the uterus, acting just as worms in the intestine. The first is the predisposing, the latter, the exciting cause. The weakest point in this otherwise good theory, is that it hardly seems fair to call the fœtus a *foreign* body, until it has reached its full maturity, when it does, indeed, become a *foreign* body, and is expelled.

Acute Pyæmia following the Passage of a Sound.

It is a well recognized fact that a severe chill will sometimes follow the passage of an instrument into the urethra, but it is not often that we read of a case like that presented to the New York Pathological Society by Dr. G. L. Peabody. The sound was passed for a stricture in the bulbous portion of the urethra, and apparently produced but little injury. It was followed by chill and fever, and in a few days, death. At the autopsy there were well-marked signs of pericarditis, which had been recognized during life, and also acute ulcerating endocarditis, and commencing abscesses of the kidney. The blood-vessels in the neighborhood of the abscesses contained a

greater number of micrococci than had been observed by Dr. Peabody in any other case.

A Cause of Dyspepsia.

We all know, but we do not sufficiently appreciate the fact, that disturbances of the female reproductive organs can and do oftentimes produce dyspeptic symptoms, on account or through the agency of that potent factor, reflex nervous influence, about which we have had so much to say recently. Dr. George Elder calls particular attention to this by some illustrative cases in the *Lancet*, December 15, 1883. It will behoove us to carefully examine these organs, when we have unavailingly used all the usual remedies for the dyspeptic conditions, for thereby we will oftentimes throw a flood of light on some hitherto obscure and intractable cases. Malpositions (chiefly versions and flexions) of the womb, Dr. Elder finds to be the chief underlying causes of these troublesome cases.

A Sequela of Thyroidectomy.

It is but proper to note that Prof. Kocher, who has operated about 150 times for goitre (oftener than any other surgeon), has noticed an after effect, which he terms *cachexia strumii priva*, and which ensues in some cases where the whole thyroid is removed. It seems that reflex action operating on the brain produces an idiotic state, the countenance becomes brutal and they are incapable of executing any employment that demands intelligence. It is but just to state that Dr. Lardy, writing to the *Union Med.*, December 6, 1883, says that the memoir in which Prof. Kocher stated this fact to the Berlin Surgical Congress, was received with open ridicule and that Billroth, who has performed the operation 120 times, entirely denies the accuracy of the statement.

A New Cure for Bunions.

To the New York Pathological Society (*New York Med. Jour.*, December 15, 1883), Dr. L. H. Sayre presented some metatarsal bones which had been removed from either foot for bunion. The patient was a man about forty years of age, in whom the condition of the foot, which had existed for many years, gave rise to much difficulty in walking, and on two occasions had caused supuration. The metatarsal bone was removed by means of a bone forceps through an incision on the dorsum of the foot. The incision was closed with black silk, the wounds united in less than two weeks, and the patient was now able to get about with comfort and had a movable joint.

James & Sayre Report

Excision of the Urethra for Stricture.

Among the various methods recommended for the cure of stricture this one has not yet been much resorted to. In *Deutsch. Med. Woch.*, Dr. Huesner reports a case of stricture of many years' duration in the spongy portion of the urethra. He cut into the urethra from the scrotum, both behind and in front of the stricture and divided the stricture on a sound passed into it from behind. He then excised the strictured portion of urethra, and united the ends over a number 16 catheter (Windler's scale) which was left in for three days. After three months No. 20 could be passed with ease.

Dilute Solution of Corrosive Sublimate.

A very dilute solution of corrosive sublimate, one grain to a pint, has been used successfully in chronic diarrhoea. Latterly a somewhat stronger solution has been tried with good results in gonorrhoea, by Dr. J. McChesney (*Therapeutic Gazette*). He used an injection of one grain to six ounces (too strong, we think). He resorts to these injections, which he gives once every four hours, after the subsidence of the acute stage. He is very confident that properly applied this solution will effect a cure of the gonorrhoea within from eight to ten days after it has been resorted to.

The Renal Circulation.

This has lately been studied by Drs. Cohnheim and Roy. Without going into the minutiae of their elaborate methods it is sufficient to say that the organ was enclosed in a sort of plethysmograph, to which Roy has given the name of oncometer, by means of which variations in volume of the kidney can be registered. With regard to the normal circulation in the kidneys, it was found that both the respiratory and pulse waves were shown in the kidney tracing, as well as the Traube-Hering waves when these occurred.

Mullein Plant in Phthisis.

It will be remembered that about one year ago we noted that Dr. F. J. B. Quinlan had recommended this article. In the *Brit. Med. Jour.* December 8, 1883, the same gentleman reports a case of pre-tubercular phthisis in which the patient gained twelve pounds in weight in one month under the use of mullein. He considers that it possesses all the advantages and none of the drawbacks of cod liver oil.

Resorcin in Fungus Umbilici.

Gatchkoosky reports in *Vruch Vedom*, the case

of an infant two months old, with a bright red, solid, globular, umbilical tumor the size of a bean. It was fixed by a short pedicle to the bottom of the umbilical fossa. It was powdered daily with resorcin. After the first application the new growth became of a dark greyish color, and markedly shrank. Five days later the tumor fell away, and within the next few days the blennorrhæa disappeared, and a normal cicatrization of the navel followed.

Painless Paracentesis.

Since general etherization is sometimes interdicted owing to some heart trouble, etc., and since the ether-spray is disagreeable, owing to the odor of ether, the following, not very new, but practical suggestion of Dr. F. P. Stapes in the *Brit. Med. Jour.*, November 17, 1883, is worthy of note. He applies a mixture of salt and ice for about twenty minutes before the operation. This completely destroys all sensibility in the part.

Gelsemium for After-Pains.

After-pains are sometimes exceedingly rebellious, hence our readers will be pleased to learn that Dr. Holt (*N. Y. Med. Jour.*, December 8, 1883,) has used the fluid extract of gelsemium, in doses of a fraction of a drop, frequently repeated. In the case of a patient in whom opium was not tolerated, and where all other remedies had been tried, the relief from gelsemium was prompt and decided.

A New Method of Tooth Drawing.

A small square of India-rubber, pierced with a central hole, is pushed over the tooth until the upper part of the root is reached. The rubber gradually contracts, pulls on the root, and the tooth is finally enucleated without causing any pain. Four or five days complete the operation, while very slight bleeding and slight swelling of the gum are the only inconveniences. This procedure is recommended by a dentist of Geneva.

Albuminous and Purulent Urine in Children.

It is a good suggestion of Dr. Samuel J. Gees (*Brit. Med. Jour.*, November 17, 1883,) that we should examine the urine of children and infants in all obscure cases of departure from health. This practice is very rarely resorted to, and yet it may serve to unravel many a mystery. It will serve to put us on the track of a latent disease should we find either albumen or pus in the urine.

Pop-Corn Again.

This article was first recommended in the pages of the *MEDICAL AND SURGICAL REPORTER*, for the vomiting of pregnancy. It has been tried and found good by several physicians who have reported their experience, and now Dr. P. S. Root (*Detroit Lancet*, December, 1883,) adds his testimony to its efficacy, not only in pregnancy vomiting, but also all in kinds of nervous vomiting.

Camphor in Mixtures.

From the *Gaz. Hemdom.* we learn that gum arabic, by forming an emulsion with camphor, enables us to prescribe it in a fine state of subdivision. The following formula is recommended:

Camphor,	1 part.
Powdered gum arabic,	2 parts.
Decoction of linseed,	250 "
Yolk of egg,	No. 1.

Injection of Morphia for Strangulated Hernia.

In the *Vratch* Dr. Zolotnitzky reports a case of femoral hernia, strangulated for eighteen hours. All manipulation proving unsuccessful, he injected subcutaneously one-fifth of a grain of acetate of morphia in the neighborhood of the hernia. After one hour the tumor had nearly disappeared and a single touch of the finger completed reduction.

Pilocarpine in Puerperal Eclampsia.

Dr. James Murphy considers the use of pilocarpine, on account of its diuretic and diaphoretic properties, a valuable adjuvant in the treatment of puerperal eclampsia, as it reduces arterial tension at once, and gives our other remedies time to act. He reports two cases, in which it acted very favorably, in the *Am. Jour. Obstetrics*, December, 1883. He used it hypodermically in doses of $\frac{1}{3}$ of a grain.

Blisters Over the Heart.

Dr. Beverly Robinson recently told the Practitioners' Society of New York (*Med. Record*, December 22, 1883,) that he had been using blisters over the heart in certain cases of chronic cardiac disease, with enfeebled action and accompanying dyspnoea. They were cases where the ordinary methods failed to give relief. The blistering seemed to strengthen the heart's action.

Artificial Urea as a Substitute for Quinine.

The *Jour. d'Hygiène* reports that Dr. Belvouseff, of Charkow, Russia, has used artificial urea (car-

bamide) as a remedy for intermittent fever in place of quinine. It is almost tasteless, and does not depress the nervous system. In Southern Russia, the peasants have used urine as a febrifuge for centuries; this has suggested the rational use of urea to Dr. B.

The Salt Test for Albumen.

In the *Practitioner* Dr. Roberts recommends the following test: The urine is rendered slightly acid with hydrochloric acid, when to it is added a saturated filtered solution of common salt in excess. The albumen, if present, is thrown down. The same specimen of urine can be tested for sugar by adding Fehling's solution.

Sub-Peritoneal Injections of Albuminate of Iron in Chronic Anæmia.

In the *Gazz. degli Ospitali*, No. 35, 1883, Prof. A. Vachetta announces as the result of experiments on dogs that the effects of albuminate of iron are more readily obtained by sub-peritoneal administration than by any other method, and that no inconveniences result from this mode of administration.

Cirrhosis Without Alcoholism.

To the St. Louis Medical Society (*St. Louis Med. and Surg. Jour.*, December, 1883,) Dr. Bernays presented a cirrhotic liver weighing not quite a pound and a half, from a woman who never drank any alcohol. She was tapped three times, and from three to six gallons of liquid withdrawn each time. The kidneys were normal.

Syphilitic Disease of Rectum.

A case in which constitutional treatment had no effect is reported by Dr. Kelsey in the *N. Y. Med. Jour.*, Dec. 8, 1883. Two ulcers just within the anus persisted until strong nitric acid was applied, when the pain left them and in a month they were perfectly healed.

Gummata of the Penis.

There are on record a few cases of ulceration of the penis occurring some years after syphilitic infection, to which M. Ozenne (*Rev. de Chirurgie*) now adds another. In this case, the ulcer was feared to be malignant, but under the use of mercury and iodide of potassium it healed in about a month, thus proving its specific character.

Infantile Rheumatism.

Dr. J. K. P. Caldwell reports (*Louisville Med. News*, December 8, 1883,) a case of acute rheum-

atism occurring in a baby two months old. In spite of the usual treatment (salicylic acid, etc.), the child died on the tenth day of the disease, having had convulsions for two days preceding death.

Persistent Epistaxis.

There are few things more trying to the young doctor (and to the old one too) than a persistent hemorrhage from the nose. As the blood keeps dropping, dropping, dropping, so equally do the physician's spirits. Dr. Guedevo tells us in *L'Indipendente*, November 15, 1883, that he succeeded in controlling two cases with the following, given in teaspoonful doses every fifteen minutes. After some vomiting, the hemorrhage ceased: Tartate of antimony and potash, gr. ij; distilled water, f $\overline{3}$ iv.; simple syrup, f $\overline{3}$ vj.

Alcohol in Trichinosis.

Fortunately, trichinosis is a comparatively rare disease, but when it does occur, the physician who endeavors to cure it has his hands full. Hence, it is well to remember that Dr. Ferrer (*Gac. de les Hospitals, Valencia*) has had most gratifying results in one case from the use of alcohol. The disease had existed for four weeks, when this treatment was commenced. He commenced with six and increased to nine ounces daily, in sugared water, in the intervals of feeding. The patient was completely well in eighteen days.

Diphtheritic Heart Weakness.

Great care and watchfulness are necessary in convalescence from diphtheria for many reasons, and for none more so than on account of the feature noted by Herr Levy, in *Deutsch. Med. Woch.* He has noticed attacks of heart weakness and faintness, without loss of consciousness, the lesion producing which, he believes, resides in the cardiac substance itself, and is not dependent on disordered innervation.

Electricity for Strangulated Hernia.

A hernia (scrotal) as large as a man's head, was completely reduced by Dr. M. Pargamin (*Vratch*) by fifteen minutes faradization and manipulation, when three hours taxis had signally failed. The tumor was faradized in all directions.

Diphtheria vs. Pregnancy.

We are called upon to exercise unusual precautions to isolate pregnant women from cases of diphtheria, for Dr. Ollivier tells us in *Arch. Gen.*

de Med., October, 1883, that it is very likely to produce abortion.

Death from Passion.

Very few persons realize the necessity of cultivating an equable temper and of avoiding passion. With a weak heart or atheromatous cerebral arteries, the giving way to passion may cause a giving way of the heart or a blood-vessel, and thus prove fatal. It was the result of passion that caused John Hunter's weak heart to give out, and we should ever remember his sad fate as a warning.

The Milk of the Bitch.

Dr. Biarchi (*La Union de las Ciencias Medicas of Carthagena*) says that it is much richer in nutritive materials and in sulphate of lime than the milk of other animals. He therefore wisely concludes that if we can procure it in sufficient quantity, it will prove valuable in rickets and tuberculosis. He has had excellent results from its use.

Nitrite of Sodium.

This drug has been, as we know, highly recommended in epilepsy. It now seems from some observations that have been made by Drs. Murrell and Ringer, of London, that the dose usually recommended, namely twenty grains, is dangerously large. They advise that we should commence with two grains, and increase to five if necessary.

Ear Affections in Bright's Disease.

Deafness, more or less marked, is often observed in this disease. Doumerque (*Thise de Paris*) considers this condition due either to œdema of the auditory nerve, tympanic catarrh, or effusion of blood into the tympanum.

The Warm Bath.

When a hard, tense condition of the abdominal walls interferes with examination by palpation, Dr. Mai (*Rivista Clinica*, September, 1883,) places the patient in a warm bath. In a few minutes the abdominal walls become relaxed.

Salicylic Acid for Vesical Catarrh.

Dr. Boegehold (*Deutsch. Med. Woch.*) is inclined to believe that salicylic acid is as much of a specific for rheumatic and gonorrhœal catarrh as it is for articular rheumatism. When chlorate of potash has been of no avail, he has found salicylic acid and salicylate of soda to effect a cure.

CORRESPONDENCE.

The Lancet and Tartar Emetic.

EDS. MED. AND SURG. REPORTER:—

I owe you a Christmas cheer and many thanks for having *deseccrated* your last issue (December 22) with *Tartar Emetic* and the *Lancet*, which, if your Æsculapian worthies tell true, have slain ten thousand times more Philistines than ever Samson did with the jaw-bone of an ass. Will you please spare half a column to one of those old *murderers*, to confess *how* the deed was accomplished? I copy, verbatim, from a letter written and mailed to my friend, *Dr. Hiram Corson*, on the 18th instant, four days previous to your issue, a remarkable coincidence of language.

"*John Mull*, aged about 60, a healthy, industrious farmer, but who had become quite *intemperate*, after several days of extreme exposure to wet, cold and whiskey, returned home sick on the 25th of 3d month, 1829, and went to bed, where he lay, without medical attendance, and with little nursing. On the first of the ensuing month at midnight, I was called to see him. As I approached the house, his loud, stertorous breathing was quite audible in the public road. I found him profoundly comatose, the extremities cold, stiff, and pulseless; mouth and eyes set wide open; the respiration not more than five or six. I had, a year previous, treated an analogous case, and the result led me to adopt a similar course. While hastening the preparation of more general, warm, and stimulating appliances, I immediately placed the hand and arm in pretty warm water, with active bathing and friction, till it became more warm and supple, and then applied the lancet. A single drop of thick, pitchy black blood followed the blade. As the frictions were continued, there was another and another, at shorter intervals; each successive portion appearing more fluid and less pitchy, till it flowed, a stream of blood. When it had reached *six* ounces there was a very obvious change in his condition. At *ten* he indistinctly answered questions, and at *twelve* he was quite cognizant, and the bleeding was stopped. I only state the practical facts, leaving others to form their own conclusions. Convalescence was speedy and complete. This brief narrative, with change of name, would apply equally well to the other case referred to."

E. MICHENER, M. D.

Toughkenamon, Pa.

Pasteur's New Method of Attenuation.

The view that vaccinia is attenuated variola is well known, and has been extensively adopted by English physicians. If the opinion means anything, it signifies that the two diseases are in essence one and the same, differing only in degree. M. Pasteur has recently found that by passing the bacillus of "rouget" of pigs through rabbits, he can effect a considerable attenuation of the "rouget" virus. He has shown that rabbits inoculated with the bacillus of "rouget" become very ill and die, but if the inoculations be carried through a series of rabbits, a notable modification results in the bacillus. As regards the rabbits themselves, no favorable change occurs—they are all made very ill, or die. But if inoculation be made on pigs from those rabbits at the end of the series, it is found that the pigs have the disease in a mild form, and, moreover, that they enjoy immunity from further attacks of "rouget." This simply means that the rabbits have effected, or the bacillus has undergone whilst in them, an attenuation of virulence. So the pigs may be "vaccinated" with the modified virus, have the disease in a mild form, and thereafter be protected from the disease. The analogy between this process and the accepted view of vaccinia is very close. The variolous virus is believed to pass through the cow, and there to become attenuated, so that inoculations from the cow-pox no longer produce variola in the human subject but cow-pox (vaccinia). As an allied process, though of

those who value the help of a tenacious memory. Both memory and stomach are valuable, not in proportion to the burdens they can carry, but in proportion to their training for their part in the work of the system as a whole; and either of them is made effective as much by what is kept from it, as by what is packed into it.

Professor Germain Sée on the Tubercle Bacillus.

This distinguished French teacher declares his belief that whenever this bacillus is detected in the expectoration, tuberculosis can with certainty be diagnosed, even before the disclosure of any other physical sign, for this micro-organism is not discoverable in any other pulmonary affection, whatever be its nature or origin. M. Sée dwelt upon the importance of this sign, as by a knowledge of this fact the physician might, by early treatment, be enabled to prevent the development of the disease, not by attacking the bacillus, which is unassailable when once in the organism, but by placing the patient in such a condition as would enable him to effect the destruction of the parasite, or, at any rate, to resist its baneful influence on the system.

Anecdotes of Sir Astley Cooper.

Sir Astley Cooper is said to have been in such haste to reach his out-of-town appointments that he urged the drivers of the post chaise thus: "I give three pence a mile to a boy who drives slow, four pence to one who drives fast, and six pence to one who drives like the d——." He lived in grand style and was very fond of money. It is stated that in his last years while at a country seat he turned an honest penny by buying up disabled horses and by his surgical knowledge restoring them to health and usefulness and disposing of them at a large profit."

The Physiological Action of Coffee.

In the *Brit. Med. Jour.*, we read that according to the result of experiments recently made by Messrs. Couty and Guimaraes, to ascertain the precise physiological action of coffee, that beverage is not a preventer of tissue-waste. The maintenance of nutrition is, no doubt, improved by its consumption, as Gubler asserted; but simply because it involves an increased assimilation of nitrogenous food through improving the appetite, when not taken in excess, and thereby encouraging its consumer to take nutritious food.

Memory.

The *Med. Record* very sensibly says: A man's memory is like his stomach. To do its best work it must have good treatment. It must neither be neglected nor overloaded. It can easily be so abused by neglect, or by irregular and unsystematic employment, as to become chiefly a cause of annoyance and discomfort; or, again, it can be so overworked and heavily taxed that it becomes practically the chief organ or agent of the entire system, every other portion dwindling in its comparison. The latter course is the great danger of

sions to the *Annales d'Hygiène*: In non-smokers of average constitutions the mean temperature of the twenty-four hours amounts to 36.76° C. (or about 98° Fahr.), and the pulse-rate 72.9°. In smokers the temperature reaches 37.02° C. (98.6° Fahr.), and the pulse-rate 89.9°. Tobacco-smoking, therefore, raises the temperature 0.26° C., and the pulse-rate 16°. In persons of feeble constitutions the temperature rises 0.43° C., and pulse-rate 11.9°. Taking a mean, tobacco may be said to raise the temperature 0.29° C. (nearly 1° Fahr.), and to increase the cardiac pulsations by 12.7°. Representing the normal temperature at 1000 in non-smokers, in moderate smokers it rises to 1008; and whereas the pulse of the former may be taken at 1000, that of the smoker is 1180. It is by increasing cardiac pulsations that tobacco has such an injurious effect on some constitutions.

ulate his mental faculties. He gradually increased the quantity until he would take as much as thirty ounces (partly by drinking and partly by inhalation) in twenty-four hours. During his sober periods, his mental faculties were very bright, and his health did not seem to suffer from the indulgence.

An Interesting Inquiry.

A circular has been sent out by Dr. W. Thorn-ton Parker, of Morristown, New Jersey, which we willingly publish as a matter of general interest:

DEAR DOCTOR: In view of the fact that the matter discharged from mucous patches in syphilitic cases is inoculable, is it not, in your opinion, possible for such contagion to be conveyed through contact with the cup used in the Holy Communion?

Have you observed any case in which this accident has occurred?

If more than one case observed, please state how many.

Is it customary for the clergy, in your experience, to use a napkin to wipe the cup before passing to the next communicant?

How many do you know of who take this precaution?

Is such protection, in your opinion, necessary or advisable, and is the napkin sufficient?

The cup is passed so rapidly from mouth to mouth, is not the danger great enough for the medical profession to caution the clergy on this subject?

Those who have any facts to contribute to this investigation should send them to Dr. Parker.

Suspension of Another Journal.

The editors of the *Archives of Medicine* announce its suspension after a satisfactory existence of five years. The editors are Drs. E. C. Seguin, and R. W. Amidon. We sincerely regret this suspension for the *Archives* is a most worthy journal.

Items.

—It is proposed to erect a monument to the late Dr. J. Marion Sims.

—Fifty thousand persons died between June and September during the cholera epidemic in Egypt.

—Anatomical material is very scarce in Vienna this winter, owing to the large number of first year students.

—Dr. George Stiles, of Conshohocken, who was so long and dangerously ill, is once more attending the duties of his profession.

—Dr. J. P. McGee, of Trenton, Tenn., has recently been appointed to the professorship of Principles and Practice of Medicine in the Memphis Hospital Medical College.

—In the *Vratch*, Dr. v. Devlezersky recommends salicylate of soda in doses of 2½ drachms for migraine. One dose at the beginning of the premonitory signs, another one hour later.

—The study of histology ought to be insisted upon before permitting medical students to attempt the study of pathology; not by lectures alone, but by the use of the microscope in the laboratory.

—Egyptian Rags are hereafter to be disinfected before shipment to this country. This precaution has been inaugurated by the State Department at

the request of Surgeon-General J. B. Hamilton, of the Marine Hospital Service. Pressure under steam and such other measures as may be found to be efficient for the purpose will be used.

—In the *Detroit Lancet*, December 1883, Dr. A. B. Ballou reports a case of complete fracture of the upper portion of the left side of the forehead, and escape of brain substance with perfect recovery.

—Dr. Dudley S. Reynolds has resigned the editorship of, and sold to other parties, the *Medical Herald*, which he has so ably edited for the past five years. Drs. Edward Miller and W. H. Galt will be the new editors.

—Dr. A. Tepliaschin (*Vratch*, 1882, No. 35,) recommends a thin stream of cold water from a teapot lifted from one to one and a half feet from the abdomen, in cases of colic. He has seen it relieve pain when opium and morphia had failed.

—"Infants should never be taught to eat candy, as it almost certainly causes engorgement of the lymph channels, thus tending to develop that state commonly called the strumous diathesis." This item is from a reputable journal; if there be any truth in it, our wonder is that we ever see any children that are not strumous. Besides they are never taught, it comes "kinder natural."

—A Crematory Association has been formed in Washington, and Congress is to be asked to give it a charter. A German physician has given a lot on which to erect a crematory similar to that in Washington, Penn. One of its members says that the expense of burning a body will not be more than \$35, and that soon they may be able to reduce it to \$20.

—Six ladies have distinguished themselves as students in the South London College of Chemistry, where they have been studying with a view to passing the examinations of the Pharmaceutical Society. They intend to begin life as druggists, and are amongst the first women who have been regularly trained at a public school for this end.

—Adulteration of milk in London has, according to G. W. Wigner, F. C. S., been reduced to a science. Of three hundred samples obtained in one day from different districts, only three per cent. showed no adulteration. The average of all the milk showed nineteen per cent. of added water, and it is estimated that milkmen get \$1,330,000 annually by selling water.

—A commission on the law of insanity has been nominated in France by the Senate, under the Presidency of Dr. Duprez. The members of the Committee propose visiting the principal establishments of the insane in England, France, Belgium, and Scotland, and are employed in considering and settling the details of a new law of lunacy for France, and are taking the evidence of most of the eminent experts there on the subject.

—A Dental Institute is to be added to the Berlin University, and plans for its organization have been submitted to the medical faculty. The consideration in which American dentists who have established themselves in European cities are held and the prices which they are able to charge furnish sufficient proof that such an insti-

tution is needed in other countries besides Germany.

—"Have you given electricity a trial for your complaint, madam?" asked the minister, as he took tea with the old lady. "Electricity?" said she. "Well, yes, I reckon I has. I was struck by lightning last summer, and hove out of the window; but it didn't seem to do me no sort of good."

—A young lady in a Philadelphia seminary was heard to say that the warm weather made her "sweat." A teacher who overheard the remark reproved her in these words: "My dear, bear in mind that horses sweat, men perspire, and young ladies get in a glow."

—A good story is told by *New Remedies* of a Brooklyn druggist who was much annoyed by boys ringing his night-bell, and then decamping. He determined to lie in wait for his tormentors, and arming himself with a stick, sought a convenient ambush. By and by a man appeared and took hold of the bell-handle, when the irate druggist pounced upon him and belabored him soundly. The man had a prescription in his hand, and now seeks legal redress.

—During the performance of a thrilling play in Norwalk, Conn., lately, a well-known physician of the town, who seldom entered a theatre, was among the audience. When the part came where the heroine swallowed the poison, is dying, and her lover and friends are wringing their hands and crying, helplessly, "What can be done?" the doctor was seen to be laboring under considerable excitement. At last the terrible scene was too much for him, and, forgetting where he was, he jumped to his feet and shouted: "Give her coffee, you fools; give her coffee!" Then a friendly hand pulled him back into his seat, and the surprised actors went on with the play.

OBITUARY NOTICES.

DR. JOHNSON ELIOT.

The distinguished Dr. Johnson Eliot, who died in Washington, December 30, 1883, was one of the brightest lights in American medicine. He was descended from the colonial settlers of Massachusetts and Maryland. He was born in Washington city, August 24, 1815. In 1839 he began the study of medicine under Dr. Thomas Sewall, being at the same time steward in the Naval Hospital. He matriculated in the Medical Department of Columbian College in 1842. Immediately upon graduation, he was appointed Demonstrator of Anatomy in Columbian College, and in 1850 was appointed Professor of Anatomy in the Medical Department of Georgetown College, which department he was instrumental and foremost in giving life to. In 1869 he received from Georgetown University the honorary degree of A. M., and 1872 Ph. D. In 1861 he resigned the Chair of Anatomy and took that of Surgery in the same institution, retaining it till 1876, when he was made Emeritus Professor of Surgery and Professor of Clinical Surgery, and for the past sixteen years has been Dean of the college. In 1874 he was President of the Medical Society of the District of Columbia, and in 1877 one of the Board of Censors.

He was one of the Vice Presidents at one time of the American Medical Association, and since 1852 has been annually a delegate to the conventions of the Association. Since 1864 he has been surgeon to the Metropolitan Police. In 1861-2-3-4, he was physician to the City Small-pox Hospital, and has been an attending surgeon to the Providence Hospital, consulting surgeon to St. Ann's Infant Asylum, Columbia, and Children's Hospital, and was prominently connected with all the charitable institutions and organizations. He was an eminent surgeon, and one of the most extensive and charitable of practitioners—a friend to everybody, a man of great industry, whose social qualities endeared him to many. His death was caused by pneumonia, after a short illness of eight days.

QUERIES AND REPLIES.

Query, Iowa, writes: "Will you please give in the *REPORTER* the results of the treatment of hernia by the insertion of galvanic needles. A traveling doctor is in these parts professing to cure it by this means."

Ans.—We do not believe that this treatment is of any value, but leave the query open to others.

Dr. R. S., of New York, sends a cutting where it is said that lately in Buffalo a boy contracted hydrophobia from another boy by sleeping with him! The latter had been bitten by a rabid dog. The inquiry is as to the probable truth of the statement. Knowing nothing of that particular case we can only say that we doubt the story.

Dr. P. L. M., of Tenn.—Blistering in diphtheria is of ancient date, and has been lately defended in some quarters, but the general sense of the profession is, we think, against it.

MARRIAGES.

FOX—BROWN.—In Philadelphia, December 19, 1883, by the Rev. William Brenton Green, Jr., Dr. Charles W. Fox and Alice M., daughter of John H. Brown.

MASON—DICKSON.—In Brooklyn, N. Y., on Thursday, December 20, 1883, by the Rev. Alfred DeWitt Mason, assisted by the Rev. H. J. Van Dyke, D. D., Lewis D. Mason, M. D., of Brooklyn, N. Y., and Fannie W. Dickson, daughter of the late Hon. J. D. Witherspoon, of South Carolina.

VAN DEUSEN—SMITH.—In Philadelphia, November 28, 1883, by the Rev. John McElmoyle, Edwin H. Van Deusen, M. D., and Adelaide P. Smith, both of Philadelphia.

McSMITH—KEISER.—At the residence of the bride's parents, Tuesday, December 18, 1883, by the Rev. J. C. Behny, S. McSmith, M. D., and Miss Cora C. Keiser, daughter of Mr. J. C. Keiser, of Plainfield, Cumberland Valley, Pa.

FLINT—HAY.—At Portland, Maine, December 25, 1883, by the Rev. T. A. King, Dr. William H. Flint, of New York city, and Miss Mary Adelaide, daughter of Henry H. Hay, Esq., of Portland.

DEATHS.

HILTON.—At East Orange, N. J., on Friday evening, December 21, 1883, Dr. A. T. E. Hilton, in the seventy-first year of his age.

ELIOT.—In Washington, D. C., Sunday, December 30, 1883, of pneumonia, Dr. Johnson Eliot, aged sixty-eight years.

GARDNER.—At Vernon, Oneida county, N. Y., Saturday, December 29, 1883, after a long illness, Dr. H. Dwight Gardner, of Utica, N. Y., in the twenty-ninth year of his age.

ROGERS.—At Paterson, N. J., December 30, 1883, of pneumonia, Dr. John A. Rogers, son of Dr. Alexander W. and Anna H. Rogers, aged thirty-one years.

ORIGINAL DEPARTMENT.

LECTURE.

ON THE PROGNOSIS OF PULMONARY PHTHISIS, ESPECIALLY OF DOUBTFUL FORMS OF THE DISEASE, BY THE PRESENCE OF BACILLI IN THE SPUTUM.*

BY PROF. GERMAIN SÉE,

Member of the Academy of Medicine, Member of the Faculty of Medicine, Physician to the Hôtel Dieu, Paris, France.

GENTLEMEN: In accordance with the conclusive histological researches of Cornil and Herard, Gracher and Charcot, phthisis ought to be considered as a unity, and the kind of pneumonia attended with wasting of the lungs, and known as caseous pneumonia, is only a variety of phthisis. That which is true for phthisis in the human subject, is also true for the induced phthisis of animals, for proof of which statement I need only refer you to the brilliant experiments of Villemin. It results from these considerations that the primordial element of phthisis is, as Laennec had anticipated, a specific principle. We may add to-day that this element is virulent, transmissible, in fact, of parasitic nature, and the specific germ is none other than the bacillus discovered by Koch.

These bacilli, which present themselves under the form of thin rods, whose length equals the quarter or the half of a blood corpuscle, are met with in all the tuberculous products of men and

animals. They also occur in the secretions, and notably in the sputa, and even, though in less quantity, in the blood, the urine, and fecal matters.

They are also equally met with in the lesions of scrofula, adenitis, osteitis, and Cornil and Besnier have found them in lupus.

What well shows the influence of these bacilli on the development of phthisis, is the fact that from whatever source you obtain them, they invariably produce tuberculosis when you inoculate animals with them. They even accomplish this result more surely than tuberculous matter itself. From this point it is inferred that the bacillus is the most important element of tuberculosis. It is the unimpeachable evidence of the disease. It is plain then that we have here a valuable datum for diagnosis, and that from the presence or the absence of this parasite in the expectoration we are warranted in affirming the existence or non-existence of phthisis.

The first investigations made to discover the presence of bacilli in the sputum go back to Koch, who was speedily seconded by Ehrlich, Balmer and Frankel, Cornil and Babes, Strauss, etc. All these authorities came to this conclusion: that the bacillus exists in the sputa of all tuberculous patients, while it is wanting in patients affected with any other pulmonary complaint. The number of these microphytes varies according to different circumstances; at the same time that we cannot derive any prognostic value whatever from this variability.

These facts may be of great service when it is a question, not of confirmed phthisis, but of doubted

*Translated from advance sheets furnished by the Professor for the MEDICAL AND SURGICAL REPORTER, by E. P. Hurd, M. D.

phthisis; and it is this subject principally which I desire to speak of to-day.

We may admit three kinds of phthisis difficult to recognize:

1. *Latent phthisis*, characterized solely by a hacking, teasing cough, scanty expectoration, without modification of the respiratory murmur, or percussion dullness. In these conditions, as it is not necessary that the morbid process should go on to the destruction of the mucous membrane for the bacilli to appear on the bronchi, the examination of the expectoration may settle the diagnosis, in the absence of all stethoscopic signs.

To this same category belong those cases where hemoptysis opens the series of tuberculous accidents, the nature of the hemorrhage not being at first apparent. The discovery of the specific microbes in the bloody sputa of the patient removes all doubt. I have at this moment in the wards of the Hôtel Dieu a female patient who entered the hospital for spitting of blood, dating back only a week. Nothing in her condition seemed to indicate phthisical disorder. Nevertheless, the examination of the sputa having revealed the presence of bacilli, I made the diagnosis of tuberculosis. At this present time, a month since the entry of this woman into the hospital, there are incontestable signs of a pulmonary cavity. We can even infer from this early discovery of the bacillus, that the hemoptysis (the first sign, it may be) is not the cause, but the consequence of the tuberculosis. What confirms this view of the case is that inoculation with blood sputa of hemoptoic patients has been made on animals, and has constantly determined veritable experimental phthisis.

Après of these premonitory hemoptyses, I recall to mind that of late it has been alleged that a certain number are of arthritic origin, and get well, while others, of tuberculous origin, are certainly mortal. This opinion does not seem to be justified, for even tuberculous hemoptyses sometimes get well, and you cannot tell that hemoptysis is not tuberculous till you have failed, after repeated examination, to find the specific microbe.

The bacillus test may render great service in the diagnosis of acute miliary phthisis and typhoid fever, diseases often confounded. The presence, duly noted, of bacilli in the sputa of these patients, suffices to exclude the hypothesis of typhoid fever.

2. The *larval phthisis* are those which commence under the form of an acute disease of the respiratory organs, which masks the characters proper to tuberculosis. Here the examination of the

sputa will clear up the diagnosis.

I here present a few cases which substantiate my position.

A man, aged nineteen years, presented himself at the Hôtel Dieu on the 13th of September, with all the signs of acute lobar pneumonia. At the end of nine days defervescence did not regularly establish itself; we examined the sputa and found bacilli. The diagnosis of tuberculosis was made, and by the first of October there were marked signs of cavities in the lungs.

The same history will apply to another patient affected with pneumonia of the right lung, which was at first regarded as simple and benign. At the end of three weeks, complete defervescence not taking place, we examined the sputum, and after three unsuccessful trials, we found the bacilli in sufficient abundance, and all the signs of true phthisis soon declared themselves.

The same thing may happen in the case of bronchial patients. A young man, eighteen years old, took a violent cold, a cough set in for the first time in his life, and he entered the Hôtel Dieu; we recognized on examination only the chest signs of simple bronchitis. We examined the sputa and found bacilli. The patient at the same time got better, and thought himself almost well, when we found at the right apex moist crackling, followed by loud bubbling rales.

A man of sixty-eight years of age entered the service of M. Hayem, with a cough that had lasted a fortnight; auscultation and percussion revealed only the signs of bronchitis, but the sputum contained bacilli. Three days afterward the patient died, and the autopsy disclosed tubercle granulations in the lungs.

The same remarks are applicable to many cases of laryngitis.

A man of forty years of age was attacked several weeks previously with laryngitis. The examination of the different organs did not give any clue to the nature of the disease, whether simple, tuberculous, or alcoholic. The sputa contained a certain quantity of bacilli, and the diagnosis of tuberculosis was made. The result proved the correctness of the diagnosis.

It is well known that pleurisy often ushers in tuberculosis, but it is seldom that an accurate diagnosis can be made from the first. In these cases examination of the liquid in the pleural cavity, whether pus or serum, would be likely to render valuable assistance. M. Rabinski, interne under M. Vulpian, has communicated to me the following interesting observation:

A patient, afflicted with purulent pleurisy, re-

mained four months in a condition sufficiently grave, without, however, any evidences of tuberculosis by the ordinary physical signs. M. Dermie examined on three occasions the liquid of the pleural cavity, and once only he succeeded in finding one solitary bacillus. Three weeks afterward humid cracklings were heard at the apices, and a new examination of the pus from the pleural cavity revealed the presence of numerous bacilli. The autopsy showed later that the disease was tuberculosis.

3. A third category of phthisis difficult of diagnosis, comprehends *pseudo-phthisis* with cavities, due to causes other than tubercles; a tumor, an ulcerated syphilitic gumma, bronchiectasis, etc. In these cases the symptoms remind you of advanced phthisis, but the examination of the sputa, in showing the absence of bacilli, suffices to settle the diagnosis, and saves you from mistake.

The following case is an instance in point :

A man reduced to the last degree of physiological wretchedness, entered the Hôtel Dieu with the signs of a cavity at the apex of the lung. As this patient had no fever, we had doubts as to the tuberculous nature of the disease, and examined the sputa. Not a single bacillus could be found. At the end of a month the patient recovered his appetite, his general condition was materially improved, and he shortly left the hospital, to all appearances cured. M. Debove and M. Moussen have published similar cases.

Finally, the detection of bacilli in the sputa has enabled us to solve a much-controverted question of pathogeny, to wit, whether the chronic catarrhs of diabetic patients are due to phthisis, or have a quite special etiology. The researches of Sommermann, of Rutemeyer, of Leyden, of Merkel, of Reigel, in showing the presence of bacilli in the sputa of such patients, have proved that the phthisis of diabetes is a true tuberculosis.

COMMUNICATIONS.

DIPHTHERIA—ITS TREATMENT.

BY J. N. COONS, M. D.,

Of Palmyra, Missouri.

Diphtheria is by common consent a dangerous disease, the more so because it seeks its victims chiefly amongst our little ones, whose tissues and vital organs have so much less resistive power than those of mature years. It is *dangerous*, because the onus of its attack is upon the *gateway* of life—the *avenue* through which every particle of

nutriment, every breath of life must pass, and the congestion and swelling of whose walls and adjacent structures not only makes painful or impossible nutrition and æration, but also by its pressure deranges the blood supply of the brain, the nervous supply of the body, produces a general nervous shock, with headache, cold extremities, and aching limbs, followed by a reactionary fever of a more or less marked irritative type. The danger is further enhanced by the septic infection certain to ensue if the disease be not arrested ere decomposition of the adventitious deposits in the fauces.

The thought largely obtains that diphtheria is curable *only* by the administration of antiseptics, constitutional *antidotes* (?) to the blood poison. But alas! experience teaches that ere we can saturate the system with these antidotes (?) our patients die from the effect of the injuries inflicted by the local disease at the gateway of life—die from starvation, from asphyxia, from asthenia, from nervous prostration, *exhaustion*. Then, why not rather bend our energies to the arrest of the local mischief, and the prevention or relief of its consequences, whilst our systemic antiseptics are so *slowly* antidoting (?) the blood-poison?

About 23 years ago, in Shelby county, Mo., I first encountered an epidemic of diphtheria. It appeared in the practice of a neighboring physician some eight miles distant from Shelbyville, where I then was located. It was of a virulent type, and there were many deaths. I was shortly called to assist him. Together we tried faithfully the systemic antiseptics and the local “scotching” by caustics, *et id omne genus*, at that day so highly commended. The result was the loss of nearly one-third of our patients.

I was not satisfied, and shortly after its appearance in my own practice, I resolved that in addition to systemic treatment—antiseptic and otherwise adapted to meet varying exigencies—I would treat the local disease, not as a *specific* horror to be stamped out, but as I would any *simple* local inflammation, in accordance with the general principles of medicine and common sense, trusting that as the inflammation subsided, the false membrane, the deposit from which so much was feared would be cast off, and the septicæmia be arrested in its development, if not absolutely prevented.

To this end I adopted the following line of treatment—constitutional and local—save a few slight changes, such as later discoveries and improvements with extended experience have commended to my approval and adoption. Under it,

in the same epidemic, and in others since, I have treated many hundred cases of diphtheria, and have had the satisfaction, where I have been called early in the case, of losing but little more than one per cent.

Believing this success phenomenal, and due not to the mild character of the cases treated, nor to any superior skill on my part, but rather to the fortuitous adaptation of means to the end sought, coupled with diligent nursing, I submit in all diffidence my plan of treatment, simple though it be, to the consideration of my medical brethren.

Given, a typical case of diphtheria of average malignity, in a child of eight or ten years of age, at an early stage of the disease—for then only is treatment of most avail—I would give, if the nervous chill has not passed, a teaspoonful of tinct. opii camph. to calm the nervous shock and quiet the aching limbs, after which I would clear the alimentary canal by a mild laxative, and at once give the following:

R. Potassii chloridi (not chloratis), $\mathfrak{z}j$.
Tinct. ferri chloridi, fl. $\mathfrak{z}ij$.
Syrupi scillæ, fl. $\mathfrak{z}ss$.
Syrupi simplicis, q. s. ad. fl. $\mathfrak{z}ij$.

Misce. Sig.—One teaspoonful in a little syrup or water every three hours; to be continued throughout the disease, but at lengthened intervals, after all diphtheritic membrane shall have disappeared.

With each dose of this alterative syrup I would give (according to frequency and hardness of pulse) from two to six drops of tinct. veratri viridis, till the pulse has been reduced to normal frequency and softness, and then in lessened doses every six or eight hours, till cessation of all tendency to febrile excitation.

Should an expectorant seem called for, I would direct:

R. Tinct. sanguinariæ canad.,
Tinct. ipecacuanhæ, $\mathfrak{a}\mathfrak{a}$ fl. $\mathfrak{z}ss$.
Tinct. opii camphoratæ, fl. $\mathfrak{z}ss$.
Syrup. tolutani, q. s. ad. fl. $\mathfrak{z}ij$.

Misce.—Teaspoonful as needed to loosen or quiet cough.

From the first, food of some kind, preferably milk, soup, or other liquid or soft animal food, should be given at least as often as every three hours—say after each dose of medicine. Fruits, most vegetables, and acid syrups, are forbidden. As the vital powers weaken, cream toddy, egg-nog, and occasional two-grain doses of quinine or salicine (the last preferably in capsule, to avoid faucial irritation) serve to bridge over the period

of weakness, whilst possibly neutralizing the poison of the disease.

Local Treatment.—Believing that the systemic infection largely springs from the constant inhalation and ingestion of the putrid products of the local disease, coupled with the retention of effete matters produced by the irritative fever, I consider the local treatment quite as important as the systemic.

If hot fomentations be good for an inflamed hand, why not for an inflamed and swollen throat? We will try them; and knowing the solvent power of acetic acid over diphtheritic membrane, we will add to the fomenting water as much acetic acid as we may without irritation of the external surface (from 1-8 to 1-16 part), trusting that the inhalation of the vapors ever rising from the hot fomenting cloths will stimulate secretion and prevent deposit, if the vapor do not also redissolve membrane already formed in the fauces and air passages. The fomentation may be by flannel cloths or sacks of linseed meal reaching across the front of the neck from ear to ear, and kept frequently wetted in the hot diluted acetic acid (or vinegar in its absence), and well covered with dry flannels to preserve the heat. Should the skin become irritated, the proportion of acetic acid must be lessened, or it must be omitted altogether from the fomenting liquid, lest we have a raw surface, forming a new nidus for the further extension of the disease. For direct application to the diseased fauces, nares, etc., I have found nothing so good as a saturated solution of chemically pure acetate of lead, to which may be added, when necessary (which is rare), a non-irritant antiseptic. This solution may be best applied in spray by means of an atomizer, but a gargle is of service, and the following powder dusted upon the parts will materially assist in causing the removal of any diphtheritic deposit formed in the fauces:

R. Plumbi acetatis (C. P.) pulv., $\mathfrak{a}\mathfrak{a}$ $\mathfrak{z}j$.
Pulv. gum. acaciæ, $\mathfrak{a}\mathfrak{a}$ $\mathfrak{z}j$.

Misce. Sig.—A small quantity to be blown upon the diseased parts two or three times a day. This may be done through a roll of letter sheet.

When the larynx becomes involved, the inhalation of hot steam from a saturated solution of acetate of lead in dilute acetic acid furnishes probably as hopeful treatment as any with which we are acquainted.

Summing up.—Relieve nervous shock, clear the alimentary canal, give veratrum viride till its constitutional effect is felt in a softening and slowing of the pulse, give the iron and chloride of potassa alterative steadily throughout the disease, adding an expectorant when needed; and most important,

foment assiduously for the first few days, applying the acetate of lead freely and often to the diseased fauces. Lastly, forget not to feed liberally throughout the disease, and to stimulate and support freely by alcoholics and tonics, as the exigencies of the case call for, in the wane of the disease.

TINCTURE OF GUAIAIC IN THE TREATMENT OF ACUTE SORE THROAT.

BY JOS. B. POTSDAMER, A. M., M. D.

Read before the Philadelphia Laryngological Society.

The term sore throat being both general and vague in its application, I am still led to its use, there being no other word which would embrace, and at the same time indicate, the diseased parts which are to be treated with the remedy to which I wish to call attention. In an inflammation of the throat, we find the inflammatory action most intense at certain points; at times, the tonsils bearing the blunt; again, the posterior wall of the pharynx, etc. The tincture of guaiac has been used without reference to this point.

Before relating the cases I have had under treatment, I will quote the opinions of various authorities: H. C. Wood, in his "Therapeutics;" Trousseau, in his "Clinical Medicine;" Chas. E. Squarey, in "Reynolds' System of Medicine," and Austin Flint, Sr., in his "Principles and Practice of Medicine," make no mention of the drug in the treatment of this disease.

Stillé, in his "Materia Medica," says: "Guaiac has been recommended in tonsillitis by Dr. Hanney, of Glasgow; Mr. Bell, Dr. Carson, and Mr. Carter. According to their statements, it abates pain and inflammation with singular rapidity and uniformity." He does not seem to have had any personal experience with the drug in this disease.

Stillé and Maisch, in the "National Dispensatory," second edition, page 698, in speaking of guaiac, say: "In simple tonsillitis and diphtheria it is alleged to be very efficacious, but the former disease gets well spontaneously, and the evidence of the value of guaiac in the latter is inconclusive."

In his "Practice of Medicine," Dr. Fred. T. Roberts states that guaiacum has been supposed to exert a special influence upon the disease in question.

Phillips, in his "Materia Medica and Therapeutics," endorses the use of the drug in the following terms: "Recent clinical experience has shown that guaiac is a capital remedy in tonsillitis. Given in half-drachm doses (tincture) every four hours, it appears to abate the inflammation and to cut short the disease in a remarkable manner."

It is hardly necessary to state that Morell Mackenzie and J. Solis-Cohen are among, if not the most active, supporters of this mode of treatment.

I was first led to use this treatment in the winter of 1879, and then only after a succession of trials upon myself. During that winter I was subject to attacks of sore-throat. The first, which occurred in November of that year, was quite severe, and was entirely cured in two days. About six weeks later, after exposure to wet and cold, was threatened with another attack, having sharp pains in the region of the tonsils and difficulty in swallowing. The parts were highly congested. This attack was aborted by the prompt use of the ammoniated tincture of guaiac in half-drachm doses every three hours. Was well in twenty-four hours. Two subsequent attacks were aborted in like manner. Since then have not had a recurrence.

The following are some of the cases I have treated with the drug:

Case 1. L. F., æt. 23, German, admitted to Jewish Hospital, January 21, 1883. Had sore-throat for three days prior to admission. Complaints of pain and difficulty in swallowing—former most severe on left side. Pain and stiffness in the muscles of the back of the neck. Tonsils, pharynx, uvula, and arches of the palate, inflamed and swollen. Uvula slightly oedematous. Whitish patches on left tonsil. Some fever. Pulse accelerated. Half-drachm doses of tincture of guaiac in glycerine every three hours. A weak solution of chlorate of potassium was used as a gargle three times a day.

January 23. Throat much better. Patches on left tonsil gone. Both tonsils and uvula of normal size. Inflammation subdued. Pain was gone within twenty-four hours of the commencement of treatment.

January 25. Patient well. Appearance of throat normal.

Case 2. H. P., æt. 35, single, German, admitted November 28, 1882. Is subject to attacks of sore throat. When in health, tonsils are somewhat enlarged. Had severe sore-throat for ten days prior to admission. Temperature 103° F. Pulse 108. Posterior wall of pharynx, roof of mouth, uvula, and tonsils very much inflamed. The latter greatly swollen, filling up the entire isthmus of the fauces. Left tonsil more inflamed than the right. The parts are covered with a dirty greenish-yellow membrane. The physician who saw the case prior to admission was in doubt as to whether this was a case of diphtheria or one of acute sore-throat. Patient was very weak. Bow-

els constipated. Tongue coated. Anorexia. Severe pain in throat. Gave an ounce of epsom salts. A drachm each of tincture of guaiac and glycerine were given every three hours. A weak solution of chlorate of potassium was used as a gargle. A local application of the tincture of the chloride of iron was made twice daily.

December 1. Patient much better, swelling diminishing, patches off tonsils, pain gone.

December 3. All trace of inflammatory action has disappeared. Tonsils reduced to normal size.

December 4. Treatment stopped, patient well.

Case 3. F. B., æt. 11, admitted December 28, 1882. Has complained of sore throat for a few days prior to admission. Arches of palate, uvula, and tonsils inflamed and painful. Latter enlarged and covered with dirty greenish patches. Some fever. Treatment: Tincture guaiac twenty minims in glycerine every three hours.

December 29. Pain relieved.

January 1, 1883. Patient much better.

January 4. Patient well.

Cases 4, 5, and 6. Similar to preceding one; well in five, four, and three days respectively on guaiac treatment.

Case 7. T. B. caught cold April 29, 1883. Complained of pain in the throat and difficulty in swallowing. Arches of palate injected. Gave 45 minims of tincture of guaiac every three hours. All symptoms disappeared after the second dose had been taken.

Case 8. H. B., similar to preceding one. Cured after a few half-drachm doses of tinct. guaiac.

Case 9. W. D., æt. 14, came to M. A. Loeb Dispensary on April 25, complaining of sore-throat. Pain and difficulty in swallowing. All parts of the throat were inflamed. Ordered half-drachm doses of tincture of guaiac every three hours.

April 29. Almost well. Medicine had been taken thrice daily instead of every three hours.

May 1. Well.

Trousseau, adhering to the view that this disease gets well spontaneously, makes no attempt to cut it short. Summing up the opinions of the various authorities quoted, we must come to the conclusion that those who have given the drug a fair trial have noted the efficacy of it not only in ameliorating the symptoms, but in cutting short the disease. As Mackenzie in his work on "Diseases of the Throat," says: "In cases of deep tonsillitis the treatment required is more active, but fortunately there is a remedy which, if administered at the onset of the attack, will almost always cut short the crescent inflammation. This is guaiacum."

The practical deductions that I draw from the cases that have been under my treatment are:

1. The almost instantaneous relief from pain.

2. The improvement in deglutition which always accompanies the former.

3. The early diminution of the swelling.

4. The short course of the disease—all the cases having been practically well on the fourth day of treatment, if not sooner. As an argument against the last deduction might be urged that the disease has run its natural course and terminated by limitation, that this is not so can easily be seen by referring to the cases related, some of which were sick from three to ten days prior to the beginning of the treatment.

5. If the case comes under treatment early enough, the disease can be aborted.

Even if we were to agree with Trousseau and others, in admitting that the disease must run its natural course, we have no right to act supinely, as by the use of guaiacum we certainly ameliorate and, as I believe, cut short the disease.

1644 North 8th street, Philadelphia, Pa.

TREATMENT OF GONORRHOEA, EPIDIDYMITIS, AND ORCHITIS.

BY JOSEPH L. BAUER, M. D.,
Lehighton, Pa.

Surgeons are agreed that gonorrhœa is one of the most obstinate affections in their curriculum. Whether this is due to the peculiar construction of the urethra, to the ineffectiveness of our therapeutics, or to the want of a proper etiological and pathological basis, it is difficult to say. This much is true, that gonorrhœa gets well of itself, is relieved by certain forms of medication, is prolonged into a chronic condition, or is affected by its complications.

It has often been said that a reasonable knowledge of disease makes the physician not only cautious, but creates a doubt as to the *post hoc*, *propter hoc*, of special medication. But in no field of surgery is such wanton recklessness displayed as in the treatment of gonorrhœa. Indeed, oft-times the urethra is considered to be an iron pipe, into which all irritating nostrums can be introduced *ad libitum*. Such therapeutics have no basis whatsoever; the DISCHARGE must be cured at all hazards, irrespective of consequences. It is therefore reasonable to suppose that the complications of this disease are in great part due to the methods in use to relieve it. I think it is settled that the abortive treatment is unwise and illogical, that it does more harm than good. But unfortu-

nately, the dictum of authority has not as yet reached some of the "knowing ones," who still believe that gonorrhœa is only a "nine days' wonder." Since the "bacteria craze" has transformed our "ancient notions" of some of the infectious diseases, new forms of treatment have been directed against this disease, with the purpose of destroying the dangerous bacterium and curing it. This discovery has created new forms of medication, and has introduced bichloride of mercury, boracic acid, permanganate of potash, eucalyptol, carbolic acid, and iodoform, into gonorrhœal therapeutics.

While connected with the St. Louis College of Physicians and Surgeons, I had an opportunity of testing the merits of some of these remedies; and my experience has taught me that boracic acid and iodoform answer many indications. I have found also that iodoform *acts promptly* as soon as the disease shows itself; whilst boracic acid has a beneficial effect when it is passing off. Unfortunately, patients only consult their physician when the affection is under full headway, which would necessitate other forms of treatment. Always believing that our "radical" specialists were inflicting too much injury upon a very sensitive tube, I naturally took to the very conservative plan suggested by Prof. Louis Bauer, of St. Louis, and modified somewhat by Dr. Alex. Mullen, of Michigan City, Indiana. The treatment is about as follows:

R. Inf. sem. lini,	ex. 3 ij. p. 3 vj.
Ext. opii aquosi fluidi,	gtts. xx.
Plumbi acetatis,	grs. vj.

M. D. S.—Inject thrice daily, previously cleansing the urethra with warm water.

Since using this treatment, I have not met with a single case complicated by epididymitis or orchitis. At first glance, we can perceive the rationale of this treatment, and I omit, therefore, any therapeutic explanation.

Frequently, cases of orchitis and epididymitis come to us from other sources, and require immediate relief. Suggestions have been offered of late, which bid fair to take a permanent position in our surgical armory. Some opportunities have offered themselves to me to test them, and I hope that my experience will be of advantage to others. Up to this time, I had only made use of local applications and strappings, and whilst having a fair result, recovery was slow and irksome.

In the July number of "Braithwaite's Retrospect," I noticed an article by Edward Henderson, M. D., F. R. C. S. Ed., Shanghai, in which salicylate of soda had been used with good effect.*

Shortly afterwards two cases offered themselves in which this treatment could be tried. In one, gonorrhœa was complicated by epididymitis and enlarged inguinal glands, in the other epididymitis alone. In both twenty-grain doses of the salicylate was given every two hours, with excellent effect, resulting in re-establishing the discharge, and relieving the complication. I did not make accurate observations as to pulse, etc., not having the opportunity of seeing the patients often. Five cases are not sufficient to allow positive statements, but they warrant further application at any rate.

Whether or not the effect will be the same in acute orchitis, I cannot tell. If not, we have another therapeutic resource, which is always available, and whose efficacy is undisputed. A diffuse inflammation of the seminal tubules and contiguous tissue, leads to the exudation of inflammatory lymph. If resolution takes place, the health of the testicle is not impaired; but if the exudation organizes with fibrous tissue, the subsequent contraction exerts a baneful influence upon the physiological function of the organ. In other words, atrophy and subsequent sterility results. The object of treatment should be to prevent this. Puncture of the testicle has been suggested, and its beneficial effect demonstrated. I have performed this little operation in fifteen cases, with invariable success. Two of these cases are sufficient to illustrate the practical excellence of the method.

Case 1. A bar-keeper, whilst under the influence of liquor, had a suspicious connection, which developed an intense attack of gonorrhœa. He consulted a physician, with the usual result of a four days' cure. Epididymitis with orchitis set in; the scrotum enlarged enormously, and in consulting a physician he was informed that he was suffering from hernia, which demanded immediate operation. By the advice of a friend, he consulted me; he came into my office supported by two others—his pain was intense, his anxiety great. I examined his scrotum, made a proper diagnosis, and advised puncture. He was placed on the operating-table, and twenty punctures with a very fine tenotome made. The relief was immediate, and he could walk home unaided. The next day he returned, and I then found that I had produced a good-sized hydrocele, which was readily removed by a trocar. No further treatment was necessary, and he made a rapid recovery.

Case 2. A traveler while East was attacked by mumps. Metastasis took place, resulting in a very painful enlargement of the left testicle. A

*"Use of Salicylate of Soda in Acute Orchitis, Complicating Gonorrhœa," p. 179, July, 1883.

number of physicians were consulted, but he grew rapidly worse. When he arrived in St. Louis he could go no further. I tried every plan known to me and the authorities I consulted, without beneficial influence. The same treatment as previously suggested was carried out, with excellent effect.

There is no doubt that the bacterium enthusiasm will be fruitful in producing one good result, namely: in modifying the strength and nature of some of the mixtures that are carried in vest pockets as sure cures for gonorrhœa. It has often been a wonder to me how some physicians can use such active astringents in gonorrhœa, when they would consider it the grossest ignorance if applied in acute ophthalmia. But it seems as if the merit of their treatment consisted chiefly in checking the discharge, and not in assuaging the cause of the inflammation. But medicine and surgery is full of such surprises, and a rapid diminution of them can only be produced by an intelligent acquaintance with histological anatomy and pathological processes.

NOTES FROM A COUNTRY PRACTICE.

BY J. J. CONNER, M. D.,

Of Palmer, Ill.

As it is said in Holmes's System of Surgery, in the article on fracture of the femur, that it was not yet determined whether muscular action was capable of breaking the thigh-bone or not, I wish to record that on the 18th day of August, 1883, I was hastily summoned to see Freddie Smith, a boy of eleven years of age, rather small of his age, who, the messenger said, had been wrestling with another boy about his own size, upon the platform of the W., St. L. and P. Railroad. I found the little fellow sitting upon the truck belonging to the depot, pale as ashes, holding his left thigh with his hands. I had the patient carefully laid down upon the edge of the platform, with the left side to the outer edge of the platform. In taking a position at his feet, standing a little way from him, I noticed that the toes of the left foot "turned out" considerably. I then took a position upon the ground beside the boy, and grasping the leg below the knee with the left hand, and the middle of the thigh with the right hand, the boy was easily brought toward me, as though a joint was in the thigh bone, and at the same time eliciting that characteristic dull th-rub, th-rub of crepitus.

He was gently picked up and placed in a spring wagon, and taken home, something less than a half-mile from the place of accident.

The boy was treated in the following manner, viz: A strip of adhesive plaster was put around the foot, extending from just below the knee on one side of the leg, and under the hollow of the foot, up the opposite side of the leg to a point corresponding to the first end, and well wrapped with a roller bandage. He was anesthetized with a mixture of ether, chloroform, and alcohol. The ends of the broken bone were nicely coaptated, and extension, by the hands of an assistant, kept up till it was well padded with cotton. Splints were applied, which consisted of one running on the outside of the body from the axilla to 3 or 4 inches below the foot, and a short one extending from the perineum along the inside of the leg, and also 3 or 4 inches below the foot. Five bandages were put around the splints, to keep them in place, viz: "one around the ankle, one below the knee, one just above the fracture," which was "at the junction of the middle and lower thirds, fracture line running from inner side of thigh obliquely upwards and outwards something like the distance of two inches," another around the waist, and another around the chest, under the arms. My idea in putting the bandages on in this manner was to immobilize the joint below the fracture, and the one just above it.

The patient was now put upon a canvas cot, and extension and counter-extension applied in the following manner. The foot of the cot was raised a little, and a piece of board was put across the foot by means of a couple of inch screws, and a pulley-wheel screwed fast upon the cross-piece, and a piece of whip-cord tied to the adhesive plaster, which was put on the leg and under the foot, and run over the pulley and made fast to a small dinner-bucket. A sufficient quantity of water was kept in this bucket to make the desired amount of weight to keep the leg extended. Swelling was at no time very great. The little fellow only needed two or three doses of opium to allay pain. He had perfect control of the bladder and bowels. His appetite was always good, and he put in his time reading books which I and some of the neighbors furnished him.

On the 16th of September the long splints and extension apparatus were removed, and short splints applied, which were of the Koehler adaptable material, made pliable by soaking in hot water for a short time. The limb was well padded with cotton, and the short splints well secured by the roller bandage. He was soon allowed to go around, as he felt disposed, by the aid of crutches. There is a little shortening of the injured limb. He is now attending the village school.

The history of this accident is as follows: The telegraph operator and his assistant were standing near by the little fellows when they were wrestling, and, as is too common, were encouraging the boys to do their best. A "snap" was heard by the operator and his assistant, and immediately following the "snapping sound," Freddie was seen to give way and his antagonist fell upon him. Freddie told me that he heard the sound, himself, of the breaking bone, *before* he fell to the floor. It may be of interest to note in closing that the right leg had been broken when the boy was only two years old, by another person kicking him while he was sleeping with them at the foot of the bed.

On October 12, 1882, a Mr. Tade brought to me his little daughter, about ten years old, with the following history, viz: Ten weeks before, the little girl, while playing at a neighbor's with another child, "ran something into her foot." It was thought to be a piece of glass, as nothing could be found to prove what it was. The mother said, however, that on the ground in front of the porch from which the little girl had jumped, a piece of umbrella wire stay was found. It was thought at the time that maybe the end of the umbrella wire had run into the foot, and being old and rusty, it had set up an inflammation which had lasted until the time of bringing her to me. On inspection of the left foot, a suppurating wound was seen on the ball of the foot, about an inch from the juncture of the second and third toes. A scar was seen which showed that the foreign substance had entered the foot directly between the two toes mentioned. The child was so nervous that it was necessary to anesthetize her, which was done with a mixture of ether, chloroform and alcohol, twenty-five minutes being consumed in bringing her under its influence. On examination with the probe, a grating sound was elicited, and I made bold to say, "Yes, it is a piece of glass, from the sound of the probe upon it." I could not remove the "glass" until I enlarged the opening, and then by seizing it with the dressing forceps, I pulled out a piece of old, rusty wire, nearly two inches long, which had been there ten weeks without producing lockjaw.

She was sent home, after having the foot well bathed in warm water, with a mixture of sweet oil, glycerine, and carbolic acid to dress the foot with, and she made a most excellent and rapid recovery.

The REPORTER speaking of needles being for a long time in the body circulating around, puts me in mind of a case of my own. About six and a

half years ago I was awakened one morning by my wife, who asked me to see if I could find anything in her breast that would account for the "sticking" she felt there. Upon examining the breast closely, the point of a needle was found protruding just through the skin. I took the dressing forceps, and pulled out a cambric needle, and she knows not when or how it got there. It was at perfect right-angles with the long axis of the body. She *thinks* now, after hearing of the other cases, that she must have swallowed the needle when a child, before she could remember the circumstances of the swallowing.

HOSPITAL REPORTS.

NEW YORK HOSPITAL.

CLINIC OF PROF. WILLIAM H. DRAPER.

Reported by W. H. SEELYE, A. M., M. D.

Mitral Disease.

The patient, M. D., is a little girl, age fourteen, born in the United States. Was admitted December 2. Her father was subject to frequent attacks of rheumatism. Her mother is still living, but has never had rheumatism. She has several brothers and sisters, none of whom are troubled with rheumatism. She had measles when a baby, but has never had scarlet fever. Two years ago she suffered from St. Vitus' dance. Last summer she had an attack of rheumatism in the joints, and she complained of pain and palpitations in the cardiac region. She was told by the physician who attended her, that she had a heart disease which had begun when she was four years old. Since then she has suffered from shortness of breath on slight exertion, and she has grown steadily weaker. So eight weeks ago she was received into the Holy Family, an institution on Second avenue, and she was cared for by the sisters there, and put to bed, and kept quiet. She lost her appetite soon after, and became troubled with nausea and vomiting, and she had frequent attacks of vertigo, and saw spots floating before her eyes, and the difficulty in breathing increased. She was therefore transferred to this hospital Dec. 2; and on her admission her pulse was 72, respiration 20, and temperature 100.2°. The urine was slightly albuminous, but contained no casts, and its specific gravity was 1015.

Gentlemen: This little girl, fourteen years old, gives a history of an inheritance of rheumatism from her father. But she does not appear to have had any attack until a few months ago, though her doctor says that she has had heart disease since she was four years old. As it is not common for pericarditis and endocarditis to occur otherwise than as secondary diseases, it is possible that we have not had a correct history of this case. Almost invariably they are secondary to one of the essential fevers, Bright's disease, or rheumatism. But with this little girl I am very confident that

the statement, that she had cardiac disease before this attack of rheumatism, is a correct one, because the hypertrophy and the other signs of an impeded circulation are so great, that they could not have occurred in the short period of time since last summer. There is another interesting point in her history, and that is that two years ago she had an attack of St. Vitus' dance. For this seems to corroborate the opinion which prevails, that chorea is especially likely to occur in children who have heart disease or rheumatic affections.

Palpation.—The apex beat can be felt at a point in a line with the nipple and in the seventh intercostal space, and the cardiac impulse transmits a distinct thrill to the hand.

Percussion.—The area of precordial dullness is increased, and the external limit, instead of being half an inch to the inside, as it should be, is half an inch to the outside of the nipple, showing hypertrophy and dilatation of the left ventricle.

Auscultation.—A very loud and confused murmur is heard at the apex, which so mingles with the normal heart sounds that it is difficult to determine its relation to them.

Gentlemen: We have all the ordinary symptoms of an extensive valvular lesion here. The murmur which many of you have just now heard, is also audible behind at the left of the spinal column, at the junction with it of the sixth, seventh, and eighth ribs. There is a very decided difference of opinion among you, as to the relation which this murmur bears to the normal heart sounds. Some of you heard it following the first sound, and therefore considered it to be a systolic murmur, indicating an insufficiency of the mitral valve, and a consequent regurgitation; and others of you heard it as a pre-systolic murmur, indicating a stenosis or roughness of the valves at the mitral orifice, and consider the murmur as produced by the rushing of the blood through this unnaturally-constricted opening. As I hear this murmur, it is pre-systolic and very loud, but upon more careful examination I think I hear a double murmur, and a softer bruit occurring with the ventricular systole, and following the contraction of the auricles, which is most distinct over the mitral orifice. I believe therefore that we have here both a mitral stenosis, and a mitral insufficiency which allows of a regurgitation of the blood through the orifice, which is not tightly closed by the valves.

Now, a word in regard to the diagnostic value of heart murmurs. Perhaps there is no more serious mistake made by the physician than that of attaching too much, and a false importance, to a cardiac murmur. For murmurs sometimes exist without there being any organic disease or defect in the heart. Thus there are so-called blood-murmurs, which are due to some variation in the specific gravity, or in the quality and quantity of the blood, or to its anæmic condition and a resulting relaxation of the muscles and valves of the heart. There are also temporary non-anæmic murmurs, due to a disturbance in the heart's action for a brief period only, and sometimes there are permanent murmurs with no apparent cause and with no other indications of cardiac disease. There is no other organ in the body about the integrity of which a man is so solicitous as the heart. And to tell a person that he has disease

of the heart, is a verdict which you should never pronounce without having substantial evidence of the correctness of your diagnosis. There is another symptom which is not so important as was formerly supposed, and that is the presence of albumen in the urine. A man was formerly supposed to be doomed if albumen, or casts, were at any time found in his urine. But now it is known that albumen in small quantities, and even casts, may be present temporarily when there is no disease of the kidneys. And certain medicines, and especially the iodide of potassium, will produce a temporary albuminuria. So you must always be careful to take all the essential conditions of a disease into consideration before making your diagnosis.

If you suspect a valvular disease, you should make a physical examination to determine if there is any hypertrophy of the heart in addition to the murmur, or any pulmonary congestion, or occasional congestion of the liver and abdominal viscera.

If you find that you get all the symptoms of an obstructed circulation, then you are sure of your diagnosis; but if you do not, then you should not attach too much importance to the mere presence of a murmur, and do not on any account show your suspicions to the patient. In this case we have a very great hypertrophy, though there is no pulmonary congestion at present. But no doubt if you were to examine into her habits, you would find that she takes great pains to avoid whatever would tend to cause pulmonary congestion. Patients who are liable to this condition, learn to move with great deliberation, and so they avoid the dyspnoea which would otherwise be caused by sending the blood to the heart more rapidly than it can dispose of it. Though the physical examination does not reveal any congestion in the lungs here, or any enlargement of the liver and spleen, and though there is not, and never has been, any swelling of the limbs, still we have evidence enough of a cardiac lesion in the presence of the great cardiac hypertrophy in conjunction with a loud murmur.

Another point to which I wish to call your attention is the fact that though this child is now fourteen, and she has had heart disease since she was four years old, yet she went on with no very serious inconvenience until last summer, when she had an attack of rheumatism, and since then she has not been so well. Now the explanation is, that in all such cases the heart compensates for the obstruction in the circulation by undergoing hypertrophy, so that the patient lives in comparative comfort for a considerable period. But at last there comes a time when this hypertrophy ceases to compensate. This may occur during an attack of illness, or as the result of some sudden muscular exertion, or the patient may have attained to that age in which a general degeneration of the vital tissues begins to take place; and it is well known that hypertrophied muscles as a rule degenerate earlier than healthy textures. As soon as the power of the degenerated heart muscle becomes insufficient to overcome the obstruction to the circulation, then begins a general disturbance of the vital functions, and it is often not till then that the assistance of the doctor is solicited.

Now, what is to be done for a patient in this

condition? This little girl comes here more feeble than she has been before; her circulation is rapid and feeble, and her strength is gone. She therefore needs rest first of all. And this is a cardinal principle in the treatment after there has been a failure of compensation—namely, to put the patient to bed, and to secure absolute rest. Many who come to this hospital are relieved by this means alone.

Dietetics form an important part of the treatment of these cases. It is important to give the lungs as free play as possible, for this gives great relief to the heart. It is, therefore, necessary to avoid many of those articles which are frequently included in the diet of the sick. You must discard all of the old traditions about a sick diet, which usually consists of gruel, farinaceous substances, fruits, and sweetmeats: for these things are especially harmful in such cases. These patients need such food as will not tend to undergo fermentation in the stomach and so produce gas, which by pushing the diaphragm upwards would diminish the expansibility of the lungs. They should be fed on animal food; and whisky, wines, beer, and all fermented liquors especially should be withheld. They should use nitrogenous foods principally, so as to avoid producing a gastric catarrh and increasing thus the dyspnoea.

But when the dyspnoea is great, and the congestion of the lungs is extreme, there are certain remedies which may be employed for the purpose of giving relief. Digitalis is a medicine which is especially useful in mitral disease, and it gives the greatest relief to the symptoms which result from this cardiac lesion. It is a perfectly safe remedy to use. It has been said that it increases the force of the heart, and this is what we want it to do in these cases. It also diminishes the frequency of the heart's action, that is, it increases the diastolic interval, and so allows the ventricle to become more completely filled and gives the heart muscle a larger amount of blood to contract upon; and this is also what we want here. But this is not so good a remedy to administer in aortic regurgitation, for here it may allow the heart to become over-filled so far that the diastole is not recovered from by the enfeebled muscle. Opium is a good substitute for digitalis in this class of cases, because it stimulates the force of the heart, while it does not diminish its frequency by increasing the diastolic interval so much.

This little girl is not taking any medicine, for she does not require any cardiac stimulant at present. Her heart is regular in action and not very frequent, though it is a little feeble; and she is not suffering from any distress, and her general condition is good. She is quite anæmic, however, as is often the case after an attack of acute inflammatory rheumatism.

Where repeated attacks of rheumatism occur in patients already affected with heart disease, there is another complication which you must look out for; and that is the setting up of a new endocarditis, which is apt to assume the ulcerative form and cause the deposit of new vegetations upon the valves. And these are therefore the cases in which we are apt to see the accident of an embolism occur.

Though, as I said, this patient does not need any heart stimulant, yet her anæmia and great

muscular weakness call for treatment. So for this she is taking an effervescent mixture containing iron, and she is kept upon milk and animal food. She will probably improve steadily, and then will be comparatively comfortable for a considerable period. But her next attack of illness will probably bring her again into this condition; or after twenty or thirty years, according to her habits of living, there will finally be heart failure, and the resulting congestions of the viscera, and the other difficulties which are wont to attend an obstructed circulation. Let us hope that that day will be far off.

Downward Displacement of the Transverse Colon. Three Cases, with Autopsies.

BY CHARLES HERMON THOMAS, M. D.,
Surgeon to the Philadelphia Hospital.

[Read October 17, 1883.]

A deformity of the transverse colon, consisting in the elongation of that portion of the large intestine and its displacement downward in the form of a loop or festoon, has been observed by me in three instances in private practice. Autopsies were had in them all. In the first the most dependent portion of the gut was found midway between the umbilicus and the pubic symphysis; in the second it was deeply impacted in the cavity of the pelvis; and in the third it reached the level of the umbilicus.

A positive diagnosis was not made in any of the cases, although in two of them the striking clinical conditions present were studied with special care in association with experienced and highly skilled observers. In the second in order of occurrence, the relationship between it and the preceding one suddenly occurred to my mind, and was communicated to the operator while on our way to make the post-mortem examination. In the third case the actual condition present was strongly suspected before death. So that in both of these latter special precaution was used at the autopsies to avoid disturbing the relative position of the abdominal viscera until their location had been accurately determined.

The lesion here described seems to be of rare occurrence. Thus far I have failed to discover a single recorded case; and not until this paper was nearly completed was I able to find any published reference to the condition, however vague. Several months ago I asked the assistance of Dr. Formad, who informed me that in a series of autopsies, numbering over 2,000, which he had made, he had not observed an instance of like character. He has also kindly sent me the following note:

"UNIVERSITY OF PENNSYLVANIA, Dec. 15, 1883.

"DEAR DR. THOMAS:

"* * * I looked very thoroughly through the literature of intestinal lesions, but did not meet any record of misplacement of the transverse colon.

Very truly yours,

"H. F. FORMAD."

Case 1. Male, æt. eighty years, a retired gentleman, came under my care August, 1874, as a patient of Dr. J. J. Levick, who had placed his practice in my charge during his vacation, and who informs me that there was no previous history of abdominal disease.

The symptoms present were extreme emaciation, feebleness, anorexia, and a profuse but fitful diarrhœa. The abdomen was retracted and somewhat tender upon pressure. There was no complaint of pain except at intervals of three or four hours when the diarrhœa had ceased for a time. Coincidentally with the cessation of the diarrhœa, a tumor about five inches long and two inches wide, of firm consistency, and visible on inspection, appeared beneath the thinned abdominal walls in a transverse position midway beneath the umbilicus and the symphysis pubis. The tumor persisted but an hour or so at a time, disappearing immediately upon the return of the diarrhœa. During the periods of continuance of the tumor the pain was so severe as to rapidly weaken the patient. This condition of alternate flux and painful tumefaction was repeated several times daily until death took place. During the attendance upon the case there were associated with me Dr. Albert H. Smith and a distinguished physician from another city—a near relative of the patient. With attention fully directed toward it, and after repeated observations, we were unable to frame a reasonable hypothesis as to the exact character and origin of the tumor. Death occurred September 12, about three weeks from date of attack.

Autopsy.—In the presence of Dr. Levick and the relative mentioned, I made the abdominal section. To the former I am especially indebted for the specimen obtained, and which is still preserved. Upon laying open the abdominal cavity the transverse colon was found to be greatly elongated and proportionately narrowed, the loculi being nearly obliterated, forming a loop open at the top similar to the letter U, the most dependent portion occupying the position of and constituting the tumor as above described, *i. e.*, the horizontal portion of the loop rested upon the small intestines, midway between the umbilicus and the pubic symphysis.

Case 2. Female, æt. fifty-four years, a lady of delicate frame and refined habits of life, was under my charge for about ten months prior to her decease. During the greater portion of this period Dr. James H. Hutchinson was associated with me in the attendance. Dr. Chas. K. Mills also saw her for me during my vacation. The patient had previously been attended by a homœopathic practitioner who had diagnosed her condition as enlargement of the liver and stricture of the rectum. The latter supposed condition he had treated by the introduction of rectal bougies; this practice being afterward abandoned on account of the pain produced, and the lack of beneficial results.

Profound cerebrastrhenia from other causes, with several months of delirium, and which finally led to a fatal result, serving greatly to complicate the issues involved. The abdominal conditions which had been recognized from the beginning were thus either masked or placed entirely in abeyance during much of the time.

The more prominent symptoms recognized were (1) pain, referred chiefly to the region of the liver

and extending both upward and downward, which pain was aggravated by walking, and was described as of a dragging, tearing character, and which had existed for four years or more. It was very much relieved by the recumbent posture, and after some months spent mostly in bed almost entirely vanished.

(2) Obstinate constipation, with indications of obstruction, even a liquid passage being voided with difficulty. The capacity of the rectum to retain enemata was also diminished to two ounces.

(3) Two solid tumors, elongated in form and of the consistency of solid faeces, were discovered, located one on each side of the abdomen, and evidently just beneath the parietal structures. They were vertical in position, and about eight inches distant from and so parallel to each other, and were traced from the border of the ribs to within about two inches of the pelvic brim. This condition was observed but a few times, and at considerable intervals; at other times it was absent. The hypothesis was adopted that these masses were the ascending and descending colon, respectively, in a state of fecal impaction.

Death occurred March 30, 1882, supervening upon a severe mental shock. An autopsy was made by Dr. Wm. M. Gray two days later, Dr. Hutchinson and myself being present. To quote from Dr. Gray's notes: "Upon opening the abdomen found complete prolapse of the transverse colon. It was carried beneath the pubis and rested on the bladder. The large intestine was much narrowed, and filled throughout with hard nodulated faeces; the meso-colon was absent and the omentum, which was free from fat, was extremely atrophied; the rectum was normal, showing no evidence of stricture; the liver was of normal size, but upon microscopic examination showed marked cirrhosis."

Thus, that which had appeared to be the ascending colon proved to be the descending limb of the displaced transverse colon; and that which had seemed to be the descending colon was shown to be the ascending limb of the same malformation.

The pain which had previously been felt in the region of the liver, and which had been relieved by recumbency, had manifestly been caused by the sharp flexure of the colon contiguous to it; and the rectal obstruction by the crowded condition of the pelvis produced by the invading loop of large intestine.

Case 3. Male, æt. thirty years, a tailor's cutter, under attendance nine days prior to decease. The subject of advanced Bright's disease, with "hyaline, epithelial and granular tube casts, also mucous cells, compound granule cells, and free oil globules," he was extremely exhausted thereby. He also complained of severe pain in the abdomen to the right of and slightly above the level of the umbilicus. Upon inspection and palpation of the part no enlargement or induration was discovered; but light percussion developed an intensely tympanic sound, confined to the region described. Misplacement of the transverse colon was suspected, and the region kept under observation for any evidences of fecal impaction which might, but which did not, present. Death occurred suddenly March 19, 1883. Autopsy two days later, by Dr. Wm. M. Gray, operator, Dr. Wm. H. Burke and myself being present.

The following notes were made by Dr. Burke.
 * * * "Body rather emaciated, and showing signs of commencing decomposition. On opening abdomen, absence of fat noted, omentum normal. Peritoneum showing traces of lymph and pus, in the pelvic region especially, but no general inflammation. Transverse colon empty, distended with gas, and has a sharp flexure at its centre, bending obliquely downward and toward the right, to the level of the umbilicus, thence sharply upward to its normal position. Meso-colon intact and apparently normal, except in length. No sign of fecal obstruction at the point of flexure. Both kidneys cirrhotic; capsule adherent, and secreting structure destroyed."

Evidently the heightened tympany localized near the umbilicus, which had been previously recognized and ascribed to the presence there of a portion of the transverse colon misplaced, had in reality been so caused.

No adhesions of the displaced parts were found in any of the cases cited. The intestinal fault was probably not the cause of death in any of them. Taking them together, it will be seen that clinical conditions and post-mortem appearances agree in at least one important particular, viz.: the location of the displaced intestine in contact with the anterior abdominal wall and below its normal site.

The normal anatomical relations of the colon have a special significance in the light of these cases, from a diagnostic point of view. The ascending and descending portions of the colon are, normally, to be found in contact with the *posterior* or lumbar wall of the abdominal cavity—behind the small intestines—and are there bound closely down by reflections of the peritoneum. The transverse colon, on the contrary, is normally in contact with the *anterior* abdominal wall—in front of the small intestines—where it is loosely suspended by the transverse meso-colon, a structure of considerable length.

It therefore appears to be a practical impossibility for the vertical portions of the large intestine to become spontaneously misplaced anteriorly. But of the transverse colon, its displacement downwards—in which changed position its relation of contact with the anterior abdominal wall is retained—these cases show to be a condition of repeated occurrence.

Conclusions.—(1) Displacement of the transverse colon downward within the abdomen may be to any degree, partial or complete.

(2) Such displacement will present as solid tumor if the bowel be in a state of fecal impaction, or as a limited area of heightened resonance if the bowel be distended with gas; but in either case the displaced part is to be found in contact with the anterior abdominal wall.

(3) The occurrence of intra-abdominal tumor situated below the normal site of the transverse colon, and having the same general configuration as the colon, such tumor being of a certain consistency, and presenting evidences of being in contact with the anterior abdominal wall; or the occurrence of areas of special tympany with like outlines and similarly located, constitute diagnostic signs strongly indicative of downward displacement of the transverse colon.

Some New Facts about Astigmatism.

Read December 12, 1883, by M. Landesberg, M. D.

Astigmatism is such an abstruse subject, that it should generally only be treated before the narrower circle of physicians who have made ophthalmology a special study. And if I beg leave to lay before you the results of my observations in regular astigmatism, there must be some special reason which induces me to make exception to the rule. The results of my observations open a new insight into the nature of astigmatism; they mark a real progress in the knowledge of the latter, and furnish practical consequences, which may be utilized for the benefit of all those who are suffering from a similar trouble.

You know, gentlemen, that by astigmatism we understand that form of asymmetry of the cornea, in which the curvature of the latter is either different in the different segments of the same meridian, or in the different meridional planes. The first form is called *irregular*, the latter *regular astigmatism*. Irregular astigmatism may be either acquired or congenital. It is very often associated with irregularities of curvature in the lens, and but very seldom admits of any remedial help or of correction by glasses.

It has been the scientific dogma of our days that regular astigmatism presents, in the greater majority of cases, a congenital and unchangeable optical defect of the cornea, which can only be neutralized by the selection of suitable glasses. The development of regular astigmatism, *post-partum*, is considered to be of very rare occurrence, and to take place only in consequence of certain affections of the cornea, by spasm of the lids, and occasionally after iridectomy and extraction of cataract. In these instances, however, astigmatism is temporary only, and it generally subsides when the causal affection, which had produced the changes in the curvature of the cornea, has been removed.

My observations in regular astigmatism are in full contradiction to the prevalent opinion concerning the nature of this form of error of refraction. They have taught me that, certain conditions given, regular astigmatism may develop in any cornea; that it is apt to progress and increase in degree, when the primary cause of which astigmatism is only the effect—one of the many symptoms only of the morbid process, in which the eye actually is involved—continues to work. If you have such a case in hand, and you correct the optical effect by cylindrical glasses, you only add a new injury to the existing ones; you only aggravate the morbid process; you consolidate a disorder which is apt to be cured by appropriate treatment.

The conditions under which regular astigmatism may develop are: *Progressive myopia, with and without spasm of accommodation—spasm of accommodation in an emmetropic, myopic, and hyperopic eye.*

In my first communication on this subject in "Von Graefe's Archives of Ophthalmology," xxvii. 2, I gave the history of fourteen cases which came under my treatment, either for progressive myopia with and without spasm of accommodation, or for the most various asthenopic troubles, based upon spasm of the ciliary muscle, in

connection with myopia or hyperopia. All these cases were complicated with regular astigmatism. The degree of the latter varied from 1.36 to 1.10. An increase in the degree of astigmatism was observed in two cases of progressive myopia, in connection with the progress of the latter. The treatment instituted for the asthenopic disorders, or for the progressive myopia, had the effect not only to cure the affection proper, but also to remove astigmatism entirely. The degree of astigmatism gradually subsided, keeping pace with the decrease of the other morbid symptoms.

I am now able to corroborate my first statements by additional facts. The latter are based upon a further observation of thirteen cases, in which the *transitory character of certain instances of regular astigmatism* has been fully established.

I shall not be guilty of wearying the audience by a monotonous exposition of all these cases, however interesting they may be. A brief summary of three cases will suffice to illustrate my proposition:

Case 1. The twelve-year-old boy McE. came under my treatment October 26, 1882, on account of weakness of his eyesight, which had rendered regular work impossible. He has been suffering for the last few years from violent headaches, with which were lately associated noises in the ears. He had stammered before, but slightly and occasionally only. This disorder has now become permanent for the last few months. There were marked anæmia and nervousness; the eyelids were in constant nictitation; the external appearance of the eyes was normal; all the other organs were in good condition.

Vision of the right eye was $\frac{1}{10}$; concave $\frac{1}{2}$ increased vision to $\frac{1}{5}$; concave $\frac{1}{2}$, combined with concave cylindrical $\frac{1}{8}$, 65°, brought vision almost to $\frac{1}{2}$. Vision of the left eye was $\frac{1}{10}$; concave $\frac{1}{2}$ increased vision to $\frac{1}{5}$; concave $\frac{1}{2}$, combined with concave cylindrical $\frac{1}{8}$, 105°, brought vision to $\frac{1}{2}$. There were besides weakness of the internal muscles and marked venous hyperæmia of the retina. The boy was not able to continue reading for a few moments, not even medium large print. He turned the book soon to the right, soon to the left side, raised and lowered it, and seemed to feel easiest by holding it in an oblique position to his visual line, the head turned on the vertical axis to the left. The eyelids, which were in constant nictitation, closed spasmodically on protracted efforts of accommodation, which had besides the effect to call forth lachrymation and congestion of the ocular conjunctiva, with a sensation of intense pain and pressure in the forehead and in the temples. Photophobia was not present, and the eye could stand even strong light with great ease.

I abstained from any internal medication, however tempting it was to try to build up the system by roborantia. My treatment consisted merely in absolute rest of the eyes and in the use of duboisia, by which maximal mydriasis was kept up. With the abatement of the spasm of accommodation, which was marked by a decrease in the degree of myopia and astigmatism, and by an increase in vision, the general health improved, headaches and nervousness subsided, and stammering returned to its former condition.

The final result of the treatment, as noted down January 12, 1883, was as follows: Vision of the

right eye $\frac{1}{2}$; concave $\frac{1}{2}$ increases vision to $\frac{1}{2}$. Vision of the left eye $\frac{1}{2}$; concave $\frac{1}{2}$ increases vision to $\frac{1}{2}$. No astigmatism in either eye. The weakest cylindrical glasses at my disposal, concave $\frac{1}{10}$, impair vision. Equilibrium of the muscles perfectly restored. Retina normal.

Examination repeated June 2, showed no change in the condition of the eyes; the latter have done their due amount of work without ever causing the slightest annoyance.

Case 2. The 10 year old boy B., came under my treatment October 2, 1878, for progressive myopia and asthenopic trouble, with the following condition of his eyes: Right eye, M. $\frac{1}{16}$, V. $\frac{1}{10}$; concave $\frac{1}{8}$, combined with concave cylindrical $\frac{1}{8}$, 95°, increases vision to $\frac{1}{5}$. Left eye, M. $\frac{1}{16}$, V. $\frac{1}{10}$; concave $\frac{1}{8}$, combined with concave cylindrical $\frac{1}{8}$, 105°, increases vision to $\frac{1}{5}$. The parents of the boy are highly myopic, and there is myopia in the respective families.

A three months' treatment by means of heurteloups and atropia had the effect to increase vision to $\frac{1}{5}$ in each eye, and to remove myopia and astigmatism. In spite of the many hurtful influences to which his eyes were subjected, the latter gave no cause of complaint until the fall of 1882, when symptoms of asthenopic troubles and of irritation developed in conjunction with the reappearance of myopia. Examination made December 4, revealed: Right eye, vision $\frac{1}{5}$, with concave $\frac{1}{8}$, V. $\frac{1}{5}$, combined with concave cylindrical $\frac{1}{8}$, 90°, V. $\frac{1}{5}$. Left eye, V. $\frac{1}{10}$, with concave $\frac{1}{8}$ respectively $\frac{1}{5}$, V. $\frac{1}{5}$, combined with concave cylindrical $\frac{1}{8}$, 90°, V. $\frac{1}{5}$.

A two weeks' use of duboisia and perfect rest of the eyes improved somewhat the condition, but treatment proper had to be deferred until the summer vacation. June 25, 1883, examination showed: Vision of the right eye $\frac{1}{5}$, concave $\frac{1}{8}$ increases vision to $\frac{1}{5}$; concave $\frac{1}{8}$, combined with concave cylindrical $\frac{1}{8}$, 125°, increases vision to almost $\frac{1}{2}$. Vision of the left eye $\frac{1}{10}$, concave $\frac{1}{2}$ increases vision to $\frac{1}{5}$; concave $\frac{1}{2}$, combined with concave cylindrical $\frac{1}{8}$, 105°, increases vision to $\frac{1}{2}$. Weakness of the internal muscles, marked retinal hyperæmia. Region around the macula lutea slightly suffused.

The use of duboisia and heurteloups, and perfect rest of the eyes, gradually led to perfect recovery. The final result, noted October 3, was: Right eye, V. $\frac{1}{2}$; it bears concave $\frac{1}{10}$, but not concave $\frac{1}{8}$. Left eye, V. $\frac{1}{2}$, concave $\frac{1}{8}$, resp. $\frac{1}{5}$, increases vision to $\frac{1}{2}$. With both eyes (without the use of concave glasses), vision is $\frac{1}{2}$. Astigmatism entirely vanished. Equilibrium of muscles restored. Retina normal.

Case 3. The 14 year old boy, W., was brought to me December 27, 1882, on account of asthenopic troubles and weakness of his eyes. Examination showed: Vision of the right eye $\frac{1}{5}$, convex $\frac{1}{10}$ up to $\frac{1}{2}$, increases vision to $\frac{1}{2}$. Vision of left eye, $\frac{1}{10}$; convex $\frac{1}{10}$ up to $\frac{1}{2}$, increases vision to $\frac{1}{2}$. Cylindrical glasses do not improve vision. There is marked spasm of accommodation.

My proposed course of treatment was not agreed to at the time. The boy continued working until March, 1883, when his eyes failed totally. He resorted to another oculist, who ordered him the following glasses for near work: Concave $\frac{1}{10}$, combined with concave cyl. $\frac{1}{8}$, 120°, and prism 2°, base

inward for each eye. They acted at first like a charm, and patient was able to continue his studies for a few weeks, but then the condition changed to the worse. A modification in the glasses—concave $\frac{1}{30}$, combined with concave cyl. $\frac{1}{8}$, 120°, and prism 3°, base inward for each eye—ordered by the same physician, proved without avail. The slightest effort of accommodation provoked the most agonizing headaches, nausea, and even vomiting; vision became as bad for distant as for near objects; the general health suffered considerably. Patient lost flesh and appetite, and became of very irritable temper. In this condition he was entrusted to my care, June 28, after a treatment for dyspepsia had proved a total failure.

The examination showed: Vision of the right eye $\frac{1}{20}$; concave $\frac{1}{30}$ increases vision to $\frac{1}{10}$; concave $\frac{1}{20}$, combined with concave cylindrical $\frac{1}{20}$, 105°, gives vision $\frac{1}{10}$. Vision of the left eye $\frac{1}{60}$;

concave $\frac{1}{18}$, resp. $\frac{1}{18}$ increases vision to $\frac{1}{10}$; concave $\frac{1}{18}$, combined with concave cyl. $\frac{1}{30}$, 110°, gives vision $\frac{1}{10}$. Medium small print (Jaeger 3) is read with great effort, the book being kept close to the eyes, and askant to the visual line, the head turned on the vertical axis somewhat to the left. The lids are in constant nictitation with intervening spasmodical contractions. There is marked lachrymation and photophobia. Both retinae show intense venous congestion.

The same treatment as has been described in the second case, gave, October 2, the following result: Right eye, vision $\frac{1}{10}$; left eye, vision almost $\frac{1}{8}$. Both eyes bear convex $\frac{1}{60}$, but not a higher number. With both eyes (without the use of glasses), vision is $\frac{1}{8}$. With the help of convex $\frac{1}{60}$, vision reaches almost $\frac{1}{2}$. No trace of astigmatism. All disorders vanished. General health good.

Recent Advances in Neuro-Pathology.

The *Med. Times and Gaz.*, December 15, 1883, says: It is not many years since a definite and constant lesion was recognized in the outer part of the posterior columns of the spinal cord in cases of locomotor ataxy; and, in consequence of the general acceptance of this view as to its pathology, the name of *tabes dorsalis* has been gradually superseding the other. Recent investigations, however, have tended to raise doubt as to whether a central lesion is the one and only cause of the symptoms in this disorder. Prof. Pierret was the first to sound a note of warning when he demonstrated, at the International Medical Congress in 1881, peripheral in addition to central lesions in a case of locomotor ataxy; and in a recent number of a contemporary Mr. Page has asked point-blank whether *tabes dorsalis* may not have a peripheral origin. The patient who seems to have been, so to speak, the starting-point of this latter paper, was an old soldier, who came under observation suffering from locomotor ataxy and arthropathy, and who had suffered previously on separate occasions from perforating ulcer of each foot; and Mr. Page puts forward the hypothesis that the corn which preceded the perforating ulcer set up a peripheral neuritis which ultimately led to ordinary locomotor ataxy. The fact, however, that each great toe was affected with a perforating ulcer is much more compatible with the theory of an already existing central affection than with any other; but even if the perforating ulcer had been unilateral, it would not have formed a strong argument in support of Mr. Page's plea. Gastric crises often precede the more common symptoms of locomotor ataxy by a great many years, but no one would seriously argue that the stomach formed the starting-point of a neuritis which ultimately

led to the development of locomotor ataxy. An affirmative answer to Mr. Page's question can only be supplied by pathology. No amount of clinical study can afford convincing proof on this point. Two things are necessary for the satisfactory solution of the problem: it should be shown, first, that it is possible for peripheral neuritis to occur spontaneously; and next, that when it does so originate it is capable of giving rise to the symptoms of locomotor ataxy.

A contribution towards the elucidation of the former requirement has recently been furnished by MM. Pitres and Vaillard, who, in a series of valuable papers in the *Archives de Neurologie*, have put forward their views on the nature of peripheral neuritis not due to traumatic lesion. The subject is, comparatively speaking, a new one. Several causes have contributed to this—one of these being the general belief that a neuritis could not originate independently of any primary change in the spinal cord, or ganglia on the posterior roots; another being the imperfect methods which, up to a very few years ago, were employed in examining the nerves. Their papers are based on the careful study of nine cases in which peripheral neuritis existed, not originating in an injury. Three of these were cases of cerebral hemorrhage, two were cases of locomotor ataxy, two of Pott's disease, one of double herpes zoster, and one of leucocythæmia. In none of the cases was any alteration in the nerves perceptible to the naked eye. They were of normal color, and were neither softened, indurated, reddened, nor cedematous. The microscope alone enabled the authors to detect any alterations. The changes closely resemble those found in the peripheral portion of a divided nerve. In both instances there is at first swelling of the nucleus of the nerve-fibres, and segmentation of the myelin, advancing to complete destruction of the cylinder-axis and of the path of Schwann; in both instances,

too the destroyed fibres may be regenerated, or at any rate may be replaced by newly-formed ones. But though the processes present these analogies, it must not thereby be assumed that they are identical. The form of neuritis under consideration has not the regular, uniform evolution observed in "Wallerian" degeneration; sometimes it runs a very rapid course, at others a very slow one. There is also some evidence that spontaneous neuritis may be propagated towards the central parts, which does not occur after division of the nerve. The changes affect exclusively, at the onset at any rate, the nerve-fibres themselves, the connective tissue remaining normal during a comparatively long period, and only becoming thickened when the nerve-tubes are already deeply involved. Even in cases where the neuritis appeared to be associated with primary changes in the nerve-centres, the authors did not find the changes continuous between the spinal cord and the affected nerves; the nerve-trunks in the intervening portions often appear to be quite healthy. All peripheral nerve inflammations do not give rise to appreciable nutritive or sensory disturbances; these probably only occur when the proportion of affected fibres is somewhat considerable. They vary in their nature according to the function of the affected nerve and the degree of the change. Amongst the affections resulting from peripheral neuritis, described in this paper, are eschars of rapid formation, ulcers with no tendency to heal, vesicular herpetic eruptions or pemphigoid bullæ, perforating disease of the foot, chronic œdema, arthropathy, and malnutrition of the nails. Local anaesthesia was not constantly present. From a pathological point of view the authors make five distinct types:

1. Fragmentation of the myelin into masses.
2. Fragmentation of the myelin into balls.
3. Fragmentation of the myelin into fine granulations.
4. Atrophy of the tubes, with amber-colored granulations in the interior of the path of Schwann.
5. Complete atrophy of the nerve-tubes.

The second requirement—namely, that it should be shown that the symptoms of locomotor ataxy can be produced by a peripheral lesion—has quite recently been fulfilled by M. Dejerine, who, in a short communication to the *Gazette Médicale de Paris* (No. 44), gives an account of two cases which during life presented certain characteristic symptoms of locomotor ataxy—*e. g.*, marked incoördination, anaesthesia, and analgesia of legs, and loss of the patellar tendon reflex—and in which, after death, the spinal cord was found to be perfectly normal, whilst the peripheral nerves presented a high degree of neuritis. No indication is given as to the duration of the disease in either of these cases, and it seems fair to suppose that, had the disease lasted longer, the spinal cord might perhaps have been found to be involved. This, however, is not M. Dejerine's opinion, as he proposes to group his cases apart from the ordinary disease, calling them peripheral tabes, in opposition to the spinal disease. If, however, a differential diagnosis can only be made by the aid of the microscope after elaborate chemical processes have been followed out, it is a distinction that is hardly worth making, and it

will be more rational to admit that locomotor ataxy may be due to a peripheral lesion.

The Treatment of Violent Delirium in Fever Cases.

Dr. James W. Allan thus writes in the *Lancet*, December 15, 1883:

The management of violent delirium constitutes one of the most difficult tasks of those having the charge of fever cases. The following remarks are meant to apply to typhus and enteric, and to severe attacks of delirium in these diseases.

Mild muttering delirium clearly does not call for active treatment; it is best met by such gentle measures as shaving the head, applying evaporating lotions to the scalp, sponging the skin with lukewarm water and vinegar, etc. Even that form of delirium, common in typhus, in which the patient insists on getting out of bed to go to his work, etc., may generally be controlled easily by a skillful nurse, who has only to use persuasion and gentle restraint to keep the patient in order. Sometimes such cases insist on sitting on a chair by the fire or going round the ward on a tour of inspection, and I have known an old and experienced nurse gratify these whims with the best possible result. The patient gladly returns to bed after the exertion, feeling tired in body but satisfied in mind, and frequently falls into a refreshing sleep. Of course such liberties could be accorded in certain cases only, and under the personal supervision of an old experienced nurse. The cases which are difficult of management are those in which the delirium assumes a wild or fierce character. The worst cases of all are those in which there is pulmonary complication. When a muscular young man is seized with violent delirium at an early stage of illness, before his strength has been seriously impaired, great trouble is usually in store for those in charge. As a rule, the patient is in a state of terror or apprehension. He thinks that he is in danger of being murdered, or he believes that he is about to be consigned to hell fire. He is simply desperate, and this constitutes the great danger of the case. Sometimes he is cunningly planning his escape. At this stage he must be closely watched. There is a peculiar look about the eye, not easily described, but once seen readily recognized again. There is also change of manner, questions are answered abruptly, or an obstinate silence is maintained. The man is in a dangerous state; a violent attack may occur at any moment. Every trivial action, every careless word of the attendants, has for him a sinister meaning. Without warning he may spring from the bed and dash through a window. The probability is that the patient has not slept for some time, and recognizing his dangerous condition, the medical attendant is naturally anxious to administer a draught, so as to secure deep, refreshing slumber. But, to his great annoyance, the patient absolutely and doggedly refuses to swallow a drop, and for the very good reason that he believes an attempt is being made to poison him. This reminds one of the notions of the insane; and there can be no doubt that the delirious patient is temporarily insane. It may be that the attempts to get him to swallow the draught have roused the man to active resistance, and his violence may be so extreme as to ne-

cessitate the help of several persons and the application of mechanical restraint. The latter should never be resorted to when it can possibly be avoided; but when it must be employed, let it be done quickly and effectively. Plenty of help should be obtained, for if the patient is strong, and one or two persons try to put him under restraint, the result may be a severe and prolonged struggle between the patient and attendants—an exasperating kind of exertion, which is bad for all concerned. The patient should be gently, but firmly, overpowered, when, as a rule, feeling helpless, he will submit. The “jacket” and “sheet” should then be employed, great care being taken to make sure that the long sleeves of the jacket are bound firmly round the patient’s wrists, otherwise he will withdraw his hands and soon set himself free. When the jacket and sheet have been properly adjusted the patient is secure, but it is not desirable that he should be kept tied up a minute longer than is necessary. If he still refuses to swallow the draught, what is to be done? A hypodermic injection of morphia might be given, but I confess to a prejudice against this practice in fever cases, from a fear of causing local irritation, boils, etc., and, besides, the pain inflicted by the thrust of the needle, though slight, would confirm the patient in his belief that he was in the hands of the enemy.

I find the following method to work well: Morphia suppositories are administered till the patient becomes quiet and drowsy. He is then manageable. The jacket and sheet can be removed, and warm dry flannels, etc., put on. The probability is that he can now be got to take a draught, or at least to swallow passively. If he still refuses, morphia suppositories can be administered as required. As to the nature of the draught, I may state that I adhere to the hydrate of chloral, long ago tried and recommended by Dr. James B. Russell in the treatment of fever cases. When there is simply insomnia, twenty or twenty-five grains of chloral hydrate in syrup (repeated, if necessary, in an hour) generally secures good sleep for an adult. When, however, there is violent delirium, the addition of five or ten minims of solution of muriate of morphia causes the end in view to be more rapidly and effectually attained. But this combination of chloral and morphia is well known to be a formidable one; it requires to be carefully administered, and the effects must be closely watched. When the narcotics require to be given for a long time on account of persistent delirium, it is convenient to prescribe a mixture, each dose of which contains ten grains of chloral and five or ten minims of solution of muriate of morphia, the interval between the doses being determined by the effect produced. Respiratory embarrassments, lividity of nails, etc., are serious contra-indications to the use of narcotics. When suppositories and draughts have both been given in a case, this should be well borne in mind so as to estimate the combined effect. In the treatment of violent delirium in fever, narcotics wisely given may save life; improperly given, they may hasten, or even directly cause, death. In prescribing them, no routine practice can be adopted, and their administration demands the most careful personal supervision of the physician in attendance.

Syphilitic Stenosis of the Œsophagus.

We take the following from the *Med. Times and Gaz.*, December 15, 1883:

Syphilitic disease of the œsophagus is rare, or, at any rate, very little attention has been given to it. In a paper in the *Berliner Klinische Wochenschrift*, No. 33, Dr. Lublinski relates two cases which occurred in his practice.

The first occurred in a man twenty-nine years of age, who came under observation in November, 1880, complaining of difficulty in swallowing solid food. This symptom had existed three weeks, and was getting worse. There was no history of his having swallowed any corrosive, and there was no evidence of pressure on the œsophagus from any tumor in the neck or mediastinum. On the uvula there was a scar, but otherwise the pharynx and the œsophagus (so much as was visible) were healthy. The larynx was movable, and not diseased. A medium-sized sound was passed without difficulty to the level of the sixth dorsal vertebra, where it met with an insuperable obstruction. A small-sized bougie could be passed through the stricture, which communicated to the hand a feeling of roughness. There was a distinct history of syphilis, ten years before. The patient was treated with iodide of potassium, and bougies were not used. At the end of eight days there was no improvement, and the patient was suffering from palmar psoriasis. The iodide was increased to thirty grains daily. At the end of three weeks there was marked improvement; the sound could be passed, though with some difficulty; and the patient could swallow solid food, though he experienced a sensation of soreness and pressure behind the sternum when the food was too solid. In the course of some weeks, under treatment with iodide, these symptoms quite disappeared, and a sound could be passed without difficulty. The patient was apparently cured in March, 1881.

The second case was a man aged fifty-four, who came under treatment for an affection of the tongue, and pain in swallowing, in November, 1881. For eight weeks he had been unable to swallow anything but liquid and soft food, and the latter gave him pain between the shoulders and behind the sternum. On the left side of the tongue, near the tip, was a hard ulcerated tumor the size of a bean; the edges of the ulcer were sinuous and considerably thickened, and around the ulcer was a red areola. The tumor was said to have been growing gradually and painlessly until fourteen days before, when it began to ulcerate. The glands about the jaw were a little swollen; the pharynx and larynx were healthy. At the level of the fifth cervical vertebra the œsophageal sound met with an obstruction, which only permitted a fine bougie to pass. The patient showed no other signs of disease. He had been infected with syphilis twenty-two years before, for which he had been treated, and during the subsequent years he had had occasional signs of the disease. Under treatment with iodide of potassium the tumor in the tongue diminished, lost its hardness, and healed, leaving a puckered scar. The œsophageal stricture was treated by the daily passage of bougies, at first with little benefit; but, as the iodide was pushed up to forty-five grains daily, an improvement gradually occurred, pains diminished,

and the patient was able to swallow solid food. The improvement continued, though in July, 1882, there was still some obstruction to a large sound, probably due to the contraction of the scar left by the syphilitic disease. Besides these two cases, Lublinski mentions several other cases.

Lublinski is of opinion that this affection of the œsophagus occurs in the later stages of syphilis, years after infection, when the patient seems to be cured. Most of the cases begin as a gummatous deposit in the submucous tissue. This deposit may undergo one of two changes—either, under proper treatment, it undergoes fatty metamorphosis and is absorbed; or the cell-proliferation continues, the intercellular substance softens and becomes gelatinous, and the mass becomes puriform, and at length ulcerates. The ulcer, in the process of healing, forms a thick scar, which has a further tendency to contract, and narrow the canal. In some cases the walls of the œsophagus may be at last converted into firm fibrous tissue, which may occupy the whole thickness, and may extend over a greater part of the surface of the canal. When the deposit undergoes fatty metamorphosis and is absorbed, no permanent stricture is produced; but when ulceration has occurred with the formation of scars, the stricture may improve, but will never be cured. As to the rarity of this affection, Lublinski suggests that the reason may be in the protection afforded by the thick stratified squamous epithelium which covers the mucous membrane of the œsophagus, and protects it from external influences; or that slight affections may be frequently overlooked both in the living patient and at autopsies, the symptoms being frequently so slight, and physical examination in the living almost impossible, so that the early stages of this disease may be overlooked; and the disease may really be more common than it is generally admitted to be.

A Case of Chromidrosis.

Dr. F. Duffy reports this case in the *N. C. Med. Jour.*, November, 1883:

Reuben Clark (col.), æt. 65 years, consulted me about three months ago on account of the red color of his perspiration, which he says has occurred occasionally during a period of about nine months. His usual occupation is that of a wheelwright, but at that time he was engaged as a farm laborer. He showed me some reddish stains on his shirt collar, and said that the colored perspiration was found over the surface of his body. A few days later he called, at my request, and brought a sheet on which he had been sleeping. This sheet had some bright red stains which he said were caused by perspiration. On several occasions after this I got him to put white cloths next to his body, and bring these to me when they would become stained. Although I had before this seen two cases of reddish exudation from the skin—one unilateral, chiefly in the right armpit, and the other about the groin—I had never seen so well-marked a case both as regards the brightness of the red, and the extent of the perspiring surface.

I was disposed to question its genuineness, but repeated observations and cross-examinations led

me to believe the old man's statements. Recently, not being expected by him, I went to his house—found him wearing a blue-checked shirt, the collar of which was distinctly stained red. He said, with the exception of the stains which I saw, he had not had any colored perspiration in several weeks. A close examination showed the stains to be chiefly on the right side.

My first knowledge of this patient was about six months ago, when he consulted me on account of partial loss of vision, accompanied with fever, pain in the eyes and around the orbit. His vision was O. D. $\frac{1}{30}$, O. S. $\frac{1}{30}$ X. Glaucoma was suspected, but tension was not sensibly increased. Ophthalmoscopic examination showed the refracting media to be clear. The results of the examination were chiefly negative. There is a slight appearance of atrophy of the nerve. He improved while taking full doses of quinine, bromide of sodium and fl. ext. of gelsemium. Fever and pains disappeared, but there was very little change in vision.

During the past five years this man has been subject to seizures which I think are of an epileptic character. He says on one occasion while in his workshop everything seemed, very suddenly, to turn upside down.

His daughter describes a sort of convulsive attack which he has at night while asleep, and which I take to be a mild form of epilepsy. These facts are stated to establish the probable neurotic origin of the chromidrosis. He complains of great languor when the sweats occur. He was treated with free doses of bromide of sodium, followed with Fellows' syr. hypophosphites, under which he has improved.

A Case of Epididymitis.

Dr. William L. Axford reports this case in the *Jour. Cut. and Ven. Diseases*, October, 1883: A young man, aged twenty-two, who had recently contracted his third gonorrhœa, asked me to see him, as he was suffering considerable pain in groin, and was afraid that his testicle was going to swell. I found that a well-marked attack of epididymitis had set in, and that the right testicle, which was involved, was the only one which had descended. Careful physical examination failed to reveal the whereabouts of the other. Rest in bed, elevation of the affected organ, anodynes, and the usual routine treatment was carried out, resulting in his recovery in a reasonable time.

On examination some days after he was sufficiently well to be about, the globus major was found enlarged, hardened, and tender, the globus minor being in a like condition. Curious to know whether his undescended testicle was of any value, and also desiring to know whether or not he was sterile, I asked for a specimen of his semen for microscopical examination. A careful examination showed that there was not a single spermatozoon to be seen, and that, though sexual desire and the ability to copulate were as perfect as ever, he was completely sterile.

An ointment was given him as follows:

R. Iodoform,	℥ ss.
Potass. iod.,	℥j.
Ung. petrolei,	℥j.

He was directed to seize the testicle so as to bring the posterior part next the skin, and to thoroughly rub in a quantity of the ointment as large as a filbert, morning and evening. His semen was examined at intervals of a fortnight.

For some weeks no spermatozoa could be seen, but at the end of two months they gradually put in an appearance, and finally the semen contained a normal quantity. The enlargement, induration, and tenderness also disappeared. Whether this happy result was due to the action of the ointment, to the massage, or whether nature would have cleared out the obstructed ducts in time, I am not prepared to say.

The Occurrence of Three Infectious Diseases in the Same Individual.

The *London Med. Record*, November 15, 1883, tells us that Dr. Prior, assistant to the Royal University Polyclinic in Bonn, communicates to the *Deutsche Med. Wochenschr.*, August 1, a case in which three different infectious diseases occurred in the same individual in the space of one month. Three children were attended on November 18 for well-marked scarlatina, with a temperature of 104° Fahr., copious eruption, and some difficulty of swallowing. Desquamation began on November 21, and proceeded normally, only one child having slight renal symptoms, until, on December 1, the two younger were attacked with rigors, headache, and malaise, and on the following day were covered with a thick eruption of varicella. On December 3, in the absence of the mother, a child from the next room, intercourse with which had been carefully avoided on account of measles, was found playing with the child, and showed signs of measles next day. The first patients were now carefully watched, and on December 13 the temperature was found to be raised, with photophobia and slight coryza; on the 15th the eruption of morbilli appeared. Its course was protracted, and caused some anxiety; but, finally, the children recovered. The cases show how the two poisons of scarlatina and varicella may be in the organism at the same time, and how measles may be conveyed by a two hours' intercourse in the prodromal stage, while the crusts of varicella are still present, the measles showing itself as soon as ten days later.

Nerve-Stretching.

The following are the conclusions of Dr. H. G. B. Wright, in the *Jour. Am. Med. Ass.*, November 3, 1883:

1. The operation was productive of good in only two of the fourteen acute cases, while it was beneficial to a greater or less degree in seven of the eight chronic cases.

2. The nerves of the upper extremities were stretched in the acute cases, and those of the lower extremities in the chronic.

3. The procedure had no effect on the case of dysæsthesia of fourteen years' standing, this being the only one of the chronic cases on which the operation was a complete failure, the result of the case of sciatica following spinal meningitis being set down as only a slight improvement.

4. The five chronic cases reported cured were sciatica.

5. No unpleasant results are reported as having followed the operation, except those in the case operated on by ourselves.

These facts are certainly reassuring, and take away from the operation the phantom of danger that might cause many an anxious physician to withhold the knife and allow his patient to suffer through months, and even years; and it adds another justifiable resource to the many with which we have been fighting neuralgias, especially of the sciatic nerves.

The Treatment of Boils and Carbuncles.

The *London Med. Record*, December 15, 1883, tells us that Dr. Rupprecht, of Hettstadt (*Deutsche Med. Wochenschr.*, May 23), regards furuncles, carbuncles, and anthrax pustules to be all dependent on an infectious cause, and the same treatment to be suitable for all of them. In boils he removes the little scab which always forms early on the top, and presses into the purulent cavity a little piece of cotton-wool moistened with spirit of ammonia. This ought to be done six or eight times at a sitting, a fresh piece of wool being used each time, and it may be necessary to repeat the treatment on the following day. In very large boils scarification, and in carbuncles a cross incision, must precede the application of the ammonia; in anthrax, the scab must be removed, and the surrounding tissue scarified in a radiating form. The part should be dressed with boracic ointment after this cauterization, and it generally heals without causing any disturbance. Boils in the external ear, where septic material is easily conveyed by the fingers, should be incised with a very small knife, and then dressed with some antiseptic which will not injure the tympanum, such as thymol, boracic acid, or iodoform.

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—Dr. A. E. Prince, of Jacksonville, Ill., sends us a reprint from the *St. Louis Medical and Surgical Journal*, October, 1883, in which he defines the true position of bromide of ethyl as an anæsthetic. He claims its applicability to short operations, since it produces anæsthesia very rapidly (which does not last long), and the patient recovers consciousness without any unpleasant sequelæ. He also advocates it as a precursor to the administration of ether.

—We have received as a reprint from the *Journal of the American Medical Association* Dr. Seiler's paper on "The Pathology of Phthisis Pulmonalis and Its Laryngeal Complications," a synopsis of which has already appeared in our pages.

—"Medical Thoughts of Shakespeare," by

Dr. B. Rush Field, of Easton, Pa., is an interesting compilation. Shakespeare had a great deal to say about doctors, medicines and diseases. The disease he refers to most frequently is syphilis, and his "favorite branch of the profession," says Dr. Field, was obstetrics. The bard, says Dr. F. "had evidently not a very high idea of the physician, and generally treats him with contempt."

—*Science*, published at Cambridge, Mass., has altered its make-up, in order to assume a more popular form. We regret that this was found necessary.

—The *Archives of Pediatrics*, edited by Dr. W. P. Watson, Jersey City, N. J., is a promising addition to our specialist journals. It is a monthly of sixty-four pages, three dollars a year, and is, as its name denotes, devoted to diseases of children. We recommend it to the profession as a periodical of a high class.

—In his late article on "The Ovarian Cell" (reprint), Dr. T. M. Drysdale, of this city, answers various criticisms on his previous writings, and certainly puts one or two of his critics in a position which, if they are sensitive, must be unpleasant for them.

—Among the new ventures of professional journalism, we mention the *Analectic*, a monthly periscope summary of the progress of medical science. Edited by Walter S. Wells, M. D., formerly editor of *Quarterly Epitome of Practical Medicine and Surgery* and *Epitome of Braithwaite's Retrospect*, etc. It is published by G. P. Putnam's Sons, New York City. Price \$2.50 per year.

—*Lippincott's Magazine* for January contains an amount of varied and entertaining reading, which gives the best assurance of the good things to be expected during the coming year. It opens with a description of the new Public Buildings of Philadelphia, written with marked ability, and copiously illustrated. Dr. Felix L. Oswald contributes a well-written article on Healthy Homes.

—*Littell's Living Age* begins its one hundred and sixtieth volume in January. Foreign periodical literature, and especially that of England, continues to grow both in extent and importance; and *The Living Age*, which presents with satisfactory freshness and completeness the best of this literature, cannot fail to become more and more valuable to its readers.

—The *North American Review* continues its active excursions into lively questions by an article on alcohol in politics in the January num-

ber, and a series of other communications on the most prominent topics of the time.

—The *Kansas Medical Journal*, a monthly published at Kansas City, Mo., makes its debut with the opening year. It is neatly printed, with a good selection of contents.

BOOK NOTICES.

•
Transactions of the Minnesota State Medical Society, 1883. St. Paul's, 1883.

A handsome volume of about 300 pages gives full testimony to the activity of the Minnesota physicians. The contents bear out the general appearance of the volume. The annual essay is on functional diseases of the nervous system, which is followed by reports on practical medicine, surgery, etc., including a number of original observations by various members of the Society.

We would call the attention of the publishing committee to the importance of having an index and a table of contents to their publications. The present volume has neither, and it is a decided drawback to its usefulness in these days of hurried reading.

Voice, Song, and Speech: A Practical Guide to Singers and Speakers. By Lennox Browne, F. R. C. S., and Emil Behnke. 1 vol., 8vo. Illustrated. Cloth, pp. 319. G. P. Putnam's Sons, New York.

The authors of this volume, one of whom is a distinguished laryngologist, the other a lecturer on and teacher of elocution, have combined their experience to write a work which shall cover the whole domain of vocal cultivation. Just what they have had in view can best be shown by a brief synopsis of the contents of the volume. The laws of sound bearing upon the voice having been discussed, a rather full description of the anatomy and physiology of the vocal organs follows. The qualities of the voice as a musical instrument are then compared, and its hygienic management is explained in detail. Some directions are inserted about the laryngoscope, and the rules of voice cultivation are succinctly stated. The ailments of the voice and the defects of speech occupy the last chapters.

The illustrations are admirable, many of them being photographs, and reproduced with the highest artistic skill. The directions for the care and development of the voice are clear and intelligible, both to the physician who is not a musical artist, and to the artist who is not a physician.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,

ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Dally Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

THE RELATIONS OF MICRO-ORGANISMS TO DISEASE.

This is really the most vital question before the medical profession to-day, because upon it hangs our whole system of therapeutics.

If it be ultimately demonstrated conclusively that disease is caused by the presence of an active, living organism, of a vegetable parasite, in the body, then must we look for a *specific* therapeutics; for if a certain disease is caused by a certain organism, and a particular drug possesses properties fatal to the life of this particular organism, such a drug is clearly indicated, and must always be resorted to in the treatment of this disease.

To-day, the sensible physician really treats symptoms.

In chills and fever and in syphilis, we always resort to quinine and to mercury; but when we get beyond this narrow limit, we really treat symptoms as they arise.

How many physicians treat diphtheria in the same way; how almost infinite are the drugs recommended for it? Does this not simply mean that we have not a specific remedy capable of controlling or neutralizing the cause of the disease? If diphtheria is caused by a micro-organism, and if we can place our hands on any one drug or combination or assortment of drugs that will always destroy the vitality of this particular organism, then have we a specific for diphtheria that will always be relied upon when the disease manifests itself.

Again, the question possesses great importance from a diagnostic point of view. If an organism, possessing certain definite characteristics, which are always revealed by the microscope and the aid of chemicals, is proven to be the cause of a certain disease, then can we be absolutely and positively sure of our diagnosis, instead of groping in the dark as we so often are compelled to do to-day.

As an aid to prognosis, also, does this question assume most important proportions. If, as Professor Flint (Sr.) believes, the proportion in which the bacilli of tubercle are found in the sputa of

tuberculous patients, holds an intimate relation to the gravity and rapidity of progress of the disease, and if this same rule holds good in other diseases, then have we placed at our service the necessary data upon which to found a much more accurate prognosis than the best of us can hope to do at present. Thus, then, we see that the question of the relations of micro-organisms to disease has a most important bearing upon the three great practical elements of our profession, namely, diagnosis, therapeutics, and prognosis.

Are micro-organisms the *cause* of disease, are they the results of disease, or do they merely occur accidentally in the course of disease?

These are the questions that hundreds of earnest and indefatigable investigators are daily striving to answer.

Both sides, or rather each of our three questions, are answered affirmatively by a certain number of physicians; but after reviewing the literature of the subject impartially, we are inclined to feel that the majority of those who are qualified to express an opinion lean towards the germ theory;—they believe that many, if not all diseased conditions, are produced by the entrance into the body of micro-organisms.

We are all familiar with the researches of Koch, and we know that many distinguished investigators have joined him in the belief that the bacillus is the cause of tuberculosis, while there are also some who oppose this view.

Gradually, micro-organisms are being found in one disease after another, and experiments are being constantly performed to determine their relation to these various diseases.

Dr. Julius Dreschfeld made a most interesting address on this subject at the late meeting of the British Medical Association, from which it can be plainly seen that he accords a high place to micro-organisms in the etiology of disease. He believes that they gain access to the system either by inspiration, through the alimentary tract, or through a denuded cutaneous surface. He seems to believe that sufficient evidence has been adduced to prove that erysipelas, septicæmia, gonorrhœa, glanders, splenic fever, relapsing fever, and tuberculosis, are

due to micro-organisms. Of course he admits, what we must all hold, that these parasites must find suitable soil, else they cannot produce disease; that some condition of the system must be present, else they cannot work mischief. What these conditions are, we do not know.

Our own Dr. Formad is the only investigator who has thus far taken up this side of the question, and his researches are confined to one disease.

While so much uncertainty surrounds this grave question, it is not well for us to accept absolutely any doctrine; let us remain unbiassed and unprejudiced, ready to receive and to carefully weigh all evidence *pro* and *con*.

The field of investigation is so full of earnest and capable laborers, that it would seem that we will not have long to wait until this 'germ theory' has been either absolutely and undeniably received or rejected; and if received, until we have definite and specific information about the nature and properties of each particular organism.

If they are proven to be the causes *per se* of disease, and if we can find certain drugs possessed of the power of robbing them of their baneful influence and of correcting the condition of the system essential for their active life, then have we at last placed medicine upon the pinnacle of an *exact* science, to which she has been aspiring for so many hundreds of years.

CURATIVE HYGIENE.

The average physician pays too little attention to the potent agency of curative hygiene; he relies too implicitly upon the drug treatment of disease, and then he wonders why some of his patients who *ought* to get well fail to do so.

We know that the zymotic diseases are caused by unsanitary surroundings; yet, when called to such cases, how many physicians inquire into the hygienic conditions and remedy those that are faulty? Do not the majority merely write out a prescription after making the diagnosis, and hurry off to the next patient? How rarely are directions given for the patient's diet, unless some of the friends ask the question?

We do not mean to belittle the influence of drugs; there is a tendency to do so in certain directions, but with this move we cannot sympathize, since we have great faith in the curative power of drugs, and believe that the day is not far distant when our therapeutics will be placed upon a very *exact* basis.

But we desire to insist upon the great value of placing our patient's surroundings in such a sanitary condition, that pernicious agencies will not be constantly counteracting and antagonizing the curative workings of our drugs.

In the *Glasgow Med. Jour.* for December, 1883, Dr. Eben Duncan very wisely and very forcibly says:

"In every house in which he (the physician) treats a patient, he ought to be able to recognize and suggest a remedy for defects of ventilation and for defects of sewerage. These matters should not be left to ignorant tradesmen, because there can be no doubt that diseases of every kind assume a more serious character, and are more intractable in ill-ventilated houses, or an atmosphere tainted with sewage-gases. He should be able to point out any error in the position of well or cistern which renders it liable to contamination, and to apply simple tests to ascertain the quality of the water. He should be able to recognize adulterations in bread, and to detect the various dangerous conditions of the milk supply, or of butcher meat, which may seriously affect the recovery of his patient. He should be able to recognize dampness in walls, and to point out its causes and its dangers—to detect arsenic in papers and bed-hangings. He should be carefully educated in the laws of infection and disinfection, in the nature of soils, and in the effects of climate. In short, I hold a man is not properly equipped as a physician who has not studied these subjects, both in their prophylactic and in their curative aspects, as carefully as he has studied *materia medica* and pharmacy. I therefore hope that in any reconsideration of the curriculum of the medical student, hygiene will be made an integral part of the course of study. At the present time the majority of medical students get no adequate instruction in sanitary science. They frequently pass all their professional examinations, and obtain a qualification to practice, without having been asked a single question, written or oral, having any bearing on such important

matters as disinfection, drainage, water supply, and ventilation."

We have already advocated the establishment of a chair of hygiene in the regular curriculum of our medical colleges, and we do most heartily agree with Dr. Duncan that the physician who is not familiar with the doctrines of preventive and curative hygiene is minus a most important weapon in his warfare with disease.

DRAINAGE AND DIPHTHERIA.

While we are very much at sea in reference to the exact nature of the specific cause of diphtheria, stern and incontrovertible clinical experience teaches us that it is a filth disease, and that defective drainage is a prolific general cause. Numerous instances, similar to the following from the *Brit. Med. Jour.*, December 1, 1883, have been lately published, all of which tend to substantiate the idea of a filth etiology. There was recently an outbreak of diphtheria at Canterbury:

"In all the cases—eight in number—the cause was local, and there is no evidence of an epidemic. Six of the children attacked with diphtheria resided in a house which was in a most unsanitary condition; the water used for drinking purposes was found to be polluted with sewage, and a hole was discovered in a drain which ran under the parlor, allowing the sewer-gas to enter the living-room of the family. Inquiry into another case in the same neighborhood revealed a like contamination of the water, and defective drainage. There was one other case, in a different part of the city, where the water was good, but the drainage at the school which the child attended was found to be very defective."

A word to the wise is sufficient. It need not concern the practical physician, whether the cause of diphtheria is a bacillus, or a micrococcus, or a micro-anything-else; if defective drainage will produce the cause, let him remedy the defect and prevent the development of the cause.

NEW WORDS IN MEDICAL WRITING.

In examining the numerous treatises, articles, and monographs which naturally come under the eye of an editor, it has often impressed us that there is in medical language a needless excess of

terminology. New words are coined by some writers to a degree that makes the freshest dictionary antiquated, and forces one to his Greek lexicon on every page. Nothing is gained by this display of erudition. In fact, it is not sound learning. One who thoroughly knows his mother tongue and is familiar with the received and generally accepted terms of his profession, will very rarely have need to coin a new word. To do so, is quite as often a proof of ignorance as a display of pedantry.

There are crises in the history of science and thought when an old terminology must be discarded and a new one adopted, because the series of ideas to be introduced are no longer connoted by the old expressions. So there are single discoveries which demand new names. But they are rare, and often are but a faint modification of previous knowledge. Much more frequently, the application of these new words is to matters already named, and hence we come to have a cumbersome and deceptive synonymy.

We have but to turn the pages of any of the extensive medical dictionaries, to note how very many words have been prematurely born into the terminology of medicine, there to have an ephemeral existence, to throw no new light, and finally to be fossilized into a shadowy unreality in the pages of the lexicographer.

It is far better to be cautious and procrastinating about introducing new words. Before doing so, let the writer carefully study his topic and clarify his thought, to see if there is not already a word suitable to receive it. The greatest masters of style have always studied simplicity of language, and *economy* is the highest criterion of good writing; economy of words, we mean, so that the idea is conveyed in the fewest and plainest terms.

NOTES AND COMMENTS.

A Bony Tumor of the Breast.

To the Pathological Society of London (*Med. Times and Gaz.*, November 24, 1883), Mr. Durham detailed the case of a woman, aged twenty-seven,

who, two years previously, had noticed pain in the left breast, which was followed by the appearance of a tumor. This seemed to be a case of adenoid tumor, though around it was an induration, which raised some doubt as to its nature. It was indistinctly lobulated, and enclosed in a capsule. On section it was found to be of pinkish-gray color; some parts soft, some harder, some friable. The principal part had a plate, three-eighths of an inch across, of bony tissue embedded in it. Microscopically there were trabeculae of osseous tissue, with lacunae and canaliculi. The tumor was a very distinct and well-characterized sarcoma; there were abundant cartilage-cells contained in it. At the periphery there was some glandular tissue, with intracystic growths.

Tamar Indien.

It is well known that Tamar Indien is a very agreeable and a very satisfactory laxative. The *Report de Phar.*, July 1883, gave the following as its formula:

R.	Tamarind pulp,	450 parts.
	Powdered sugar,	40 "
	Powdered sugar of milk,	60 "
	Pure glycerin,	50 "
M.	Evaporate to consistence of soft extract.	
	Add—	
	Powdered senna leaves,	50 parts.
	Powdered anise,	10 "
	Essence of lemon,	3 "
	Tartaric acid,	3 "
M.	Divide into 100 boluses. Steam them, and roll in the following mixture—	
	Cream of tartar,	5 parts.
	White sugar,	} aa 35 "
	Sugar of milk,	
	Tragacanth,	2 "
	Tartaric acid,	2 "
	Powdered red sandal,	25 "
	Dry and put up in tin foil.	

A Formula for Koumiss.

We note the following formula in the *Druggist's Circular and Chemical Gazette*:

R.	Fresh milk,	5 gallons.
	Spring water,	13 pints.
	Baker's yeast,	2 "
	Simple syrup,	1½ "

Mix, and skim off the top. Then put the liquid into bottles which are to be laid on their side, from one to four weeks, in a cool place, the temperature of which must be below 70°. The different stages of the preparation are as follows: After one week the koumiss is *fresh*; after two weeks, *medium*; after three or four weeks, *old*. A champagne tap is very convenient for drawing the liquid.

No Work and Wrong Work.

It is well said by a contemporary that a common and fruitful source of low spirits is the unwise apportionment of our daily work. Too much labor, as suggested in the above quotation, especially if united with care, is sure to produce gloom; and the weary man who returns to his family at night to sadden them by his funereal aspect and his catalogue of woes, should leave off claiming sympathy for what only deserves criticism. On the other hand, nothing is more fatal to a cheerful spirit than idleness. To have nothing that we *must* do, or having it to neglect it, will throw a shadow over the lightest heart and the most sunny countenance. Regular, congenial labor, in moderation, and the consciousness of faithful performance and growing ability, are tonics to the spirits that none can afford to dispense with.

Rule for Reducing Dislocations of the Hip-joint.

We note the following in the *Polyclinic*, December 15, 1883:

Having flexed the leg on the thigh, and the thigh on the pelvis, slowly rotate the limb as far as possible, inwards or outwards, according as the toes pointed in or out before beginning the manipulation; then rapidly and forcibly rotate the limb in the opposite direction, and the head of the femur will usually slip into the acetabulum.

For example: In the iliac and the sciatic dislocations, the toes point inwards; therefore, rotate inwards as far as possible, and afterwards rotate outwards. In the pubic and thyroid dislocations, the toes point outwards; hence rotate the limb outwards still more, and then inwards.

Long-Retained Pessaries.

It may prove useful as furnishing the key-note to some obscure cases of ill-health, if we bear in mind that cases are on record where a pessary has been introduced to correct some uterine deformity, and being forgotten, has been allowed to remain for years in the vagina, acting constantly as a foreign body, provoking inflammation and supuration, and producing a variety of morbid phenomena through the agency of reflex nervous influences. Dr. C. F. Paine reports a case in the *Texas Courier-Record of Medicine*, November 1883, where a Hodge pessary, forgotten and worn for thirteen years, has, he fears, permanently injured the woman's health.

Bichloride of Mercury in Diphtheria.

If diphtheria is due to a germ, and if corrosive sublimate possesses the germicide properties that

Koch ascribes to it, we can understand why Dr. Madison Reece (*Jour. Am. Med. Ass.*, November 24, 1883), has had good results from this drug. His method of preparing this medicine is to dissolve one grain of the bichloride in four ounces of rain-water; then, if the patient is old enough to gargle and rinse the throat and mouth, he is to do so every two hours, and immediately afterwards to take a teaspoonful internally. If the disease be of a severe form, it should be administered in this way every hour. The above dose is calculated for a child of five years of age. It should be continued in smaller and less frequent doses for a week or longer.

Is Tuberculosis Spontaneously Curable?

Yes! At least so it would seem from a case reported in the *Deutsch. Med. Woch.* by Dr. Nauwerck. Four brothers of the patient had died of pulmonary tuberculosis, and in 1877 he began to cough, lost flesh and looked sick, which symptoms, after lasting one year, disappeared without treatment. Six years subsequently he died of cancer of the pylorus, and at the autopsy, the apices of both lungs were found adherent to the costal pleura, the pulmonary parenchyma was shrunken and toughened, and there were scattered patches of caseous and calcified tissue. A few typical bacilli were found in a small cavity, filled with caseous material and surrounded by thick walls.

Subcutaneous Injections of Ether.

Dr. C. E. Sheely (*Brit. Med. Jour.*, November 17, 1883), has had good results from its use as a stimulant. The dose is from fifteen minims to half a drachm. He thrusts the needle through the true skin and superficial fascia, and then enters it for about three-quarters of an inch parallel to the surface. He has never seen abscesses result. As ether is a ready solvent of fat, it is advisable to look to the leather packing of the piston of the syringe as soon as possible after using it, and to re-oil it. The ether also attacks the cement used to secure the mouth to the glass barrel, and they will, sooner or later, become loose. Moreover, as it acts upon "celluloid," a syringe made of this material should not be used. He gives the preference to glass. *Ans. & Surg. Rec.*

Catarrh of Ethmoid Cells and Frontal Sinus and Nasal Canal, Caused by Maggots.

Dr. Fred. Humbert reports some cases in the *Jour. Am. Med. Ass.*, December 8, 1883. The fly deposits the eggs in the nostrils, and they there

develop. Their skin is horny, hence remedies will not readily act upon it. He recommends carbolic acid injections and hypnotics. When the maggots are mature, they drop out of their own accord; and since they have no reproductive power, there is a natural limit to the disease, if we can support the patient's strength. Some cases have terminated fatally.

Prostatic Gout.

Dr. Reginald Harrison calls attention to this condition in the *Lancet*, November 24, 1883. The attacks usually come on at night, more frequently in persons of a gouty diathesis, who have previously remained free from the more ordinary attacks of gout. The urine is loaded with lithates, and is invariably of an acid and irritating character, whence the appropriate treatment is the use of alkalis.* There is also a chronic form, best relieved by iodide of potassium internally, and mild counter-irritation to the perineum.

Micro-organisms in Typhus Fever.

Determined not to be left out in the cold, typhus fever presents to us her micro-organisms. Drs. Frederick W. Mott and J. Blorc told the British Medical Association (*Brit. Med. Jour.*, December 1, 1883,) that during the recent epidemic of typhus fever in Liverpool, they found in the blood, during the pyrexial period, moving organisms, like minute screws, which they consider to be dumb-bell micrococci, undergoing division. As a rule, they disappeared during convalescence, though in one case they were found in large numbers in the blood after the fever had subsided.

Nitrite of Sodium.

We have elsewhere noted that Drs. Ringer and Murrell have concluded that the ordinarily-prescribed dose (20 grs.) is dangerously large. From some observations of Dr. A. H. Baines, in the *Lancet*, December 1, 1883, it seems that this drug is often adulterated with nitrate of sodium, and from this fact has arisen the supposed necessity for such large doses. If we can procure the pure drug, and we ought to do so if we use it at all, two or three grains will be the dose. Dr. Baines reports a case of *petit mal* in which its use was very beneficial.

Egyptian Tamarind Flowers in Piles.

Our correspondent, Dr. Brobst, at Litiz, Pa., states in a letter to us that he has found a wine-glassful, three times a day, of an infusion of the above flowers, a valuable, pleasant laxative, and

very useful in hemorrhoids—quite a specific, indeed. The flowers are described in the United States Dispensatory, and recommended as a nerve tonic. He obtained the flowers from Carpenter & Co., Philadelphia, which house he names, as many of the flowers offered in the market are too old.

Fœtid and Sweating Feet.

Dr. A. M. Vail (*Jour. Am. Med. Ass.*, November 3, 1883,) says that he has never known the following to fail:

R.	Aluminii et ammo. exic.,	grs. 2.
	Acidi boracici,	grs. 2.
	Aquæ simp. or rosæ,	grs. 35.

Mix. Sig.—Apply with soft sponge without rubbing, just as soon as the shoes and stockings are removed, while the feet are yet moist. This is quite necessary, as also the care not to rub.

Let this be repeated every two or three days, in the evening.

Resuscitation of Still-born Children.

In the *Vracheb. Vedomosty*, 1883, No. 560, p. 3,856, Dr. H. I. Rodzewicz, of Nijni-Novgorod, relates the case of a primipara, in which he delivered, by podal version, an infant without pulsation in the umbilical cord, or any other signs of life. Schultze's method having proved unsuccessful, the author took a large basin, filled it with hot water from the *samovar* (Russian tea-machine), added cold water until the temperature of about 35° R. had been reached, and placed the infant in the basin, leaving free only her head. In a minute or so the child began to breathe and lustily cry.

Gummatous Tumors in Muscles.

When we have presented to us a muscular tumor, it is well to inquire, and inquire searchingly, for a specific history. Syphilitic gumma of muscles, Dr. Hugh Percy Dunn (*Lancet*, November 24, 1883,) tells us, are not so very common, yet neither are they very rare. Under appropriate treatment, they will rapidly disappear, while, if not antagonized by anti-syphilitic remedies, they will eventuate in nasty, deep-seated abscesses.

An Ocular Polypus.

The appendages of the eye is an unusual seat for a polypus, yet Dr. S. Pollak reports a case in the *Jour. Am. Med. Ass.*, November 24, 1883. In a woman aged 74, blood was constantly oozing from beneath the upper lid. Vision was perfect.

On everting the lid, a painless tumor (bleeding profusely on the slightest touch) was extruded. It was twisted off with forceps, and the result was entirely satisfactory; the wound having nearly cicatrized by the next day.

Napelline for Neuralgia.

Dr. Grognot (*Bull. Gen. de Therap.*) reports a case of trigeminal neuralgia, rebellious to a variety of treatment, that finally yielded to napelline in doses of $\frac{1}{800}$ of a grain every two hours. This dose seems like infinitesimalism, but it is that which is reported.

A Good Dressing for Ulcers.

Nearly all of the usual applications to ulcers will, at times, fail, hence we note with a sense of satisfaction that Dr. Maison (*Moniteur de la Polyclinique*) finds the subcarbonate of iron very efficient. He washes the ulcer with carbolized water, dusts the iron on thickly, and applies a starch poultice. The dressing is changed twice a day.

Unusual Symptoms Following the use of Unguentum Hydrargyri Ammoniati.

In the *Brit. Med. Jour.*, December 29, 1883, Dr. Shirley Deakin reports two cases of chronic eczema in which this ointment was used. To his surprise, it set up acute attacks of eczema (in one case extending all over the body), which were exceedingly slow in disappearing.

Another Cause of Epilepsy.

Dr. Allen de Vilbis calls attention to the fact (*St. Louis M. and S. Jour.*, January, 1884), that inflammation of the lining membrane of the nasal cavities may produce epileptiform convulsions. He reports three cases in which appropriate treatment for the catarrh relieved the attacks. Here is another illustration of the power of reflex action.

The Amniontome.

Failing to meet with the success usually ascribed to the finger-nail for rupturing the membranes in labor, Dr. George F. E. Wencke, of Ninety-Six, S. C., describes a simple and ingenious device in the *Med. News*, December 8, 1883. It consists of a steel spring frame to which a small blade is attached. It is adjustable to the index finger of the right hand, but will fit any finger, both right and left. Placed in position, it will not interfere with the main joint of the finger, which can be moved at will while it is firmly attached.

Reflex Nervous Influence Again.

We have had a great deal to say lately about reflex nervous influence, but if it causes some to look behind the manifest signs for the cause of departure from health, our purpose will have been accomplished. Prof. Henoch tells us in the *Wien Med. Blatter* of a case of sudden aphasia in a three-year-old girl, which rapidly disappeared after vomiting an unchewed cherry.

Blistering in Diphtheria.

It might be well to bear in mind, in connection with other treatment, that Dr. F. W. Bartlett, of Buffalo, N. Y., reports one case (*Therapeutic Gaz.*, December 1883,) wherein the throat exudation markedly diminished, and the general symptoms greatly improved after the accidental blistering, most severely, of the abdomen, with hot turpentine. The raw belly was covered with an exudation, identical, to ordinary inspection, with that in the throat.

Foreign Bodies Swallowed and Passed per Rectum.

To the Medical Society of London Dr. Munro exhibited a portion of a chain, three inches and a quarter long, which had been swallowed by an infant aged eighteen months, and passed per anum after twenty hours.

Mr. Henry Morris outlined the case of a young man who had swallowed an aluminium pencil-case, such as might have formed a pendant to a chain. This was ejected after five days, and was then found to have undergone changes in color and substance.

Paraldehyde—Acetal—Cannabinum Tannicum.

Dr. Eickholt contributes an article on these drugs to the *Deutsch. Med. Woch.*, December 5, 1883. The two first he does not like, considering them uncertain as hypnotics, and that they possess injurious properties (such as deranging digestion, producing nausea, and the like) that more than counterbalance their virtues. Cannabinum tannicum (derived from Indian hemp), in doses of $\frac{1}{8}$ to 1 grain, he considers especially useful in neurasthenic insomnia, and in mild melancholia without delusions, but not in excitable conditions. It does not derange digestion.

Resection of Half of a Vertebral Body.

Israel, of Berlin (*Berliner klinische Wochenschrift*, No. 146, 1882), reports a case in which a patient with curvature of the spine suffered from abscess and paraplegia. Supposing that the last-named

was due to compression of the spinal cord by a purulent collection, Israel resected the twelfth rib and half of the twelfth dorsal vertebra, and was thus able to evacuate the abscess. The paraplegia was not at all modified by this interference, and the patient died at the end of thirty-seven days, after having presented symptoms of purulent pleuritis.

Catheterization of Infants.

We took occasion recently to note that the evidences of disease that would be revealed were the urine of infants and children more frequently examined would be greatly to our benefit in diagnosis. We now read in *Jahrbuch f. Kindheilde* that Hirschsprung recommends catheterization in order that we may procure the urine for such examination. He prefers a metallic catheter with a rather short end and the point solid to the eye. He scents the idea of its use being dangerous, and strongly recommends it as a powerful diagnostic adjuvant.

The Inoculation of Tubercle.

The weight of evidence seems to be in favor of the doctrine that tuberculosis is inoculable, provided the soil upon which it is deposited is suitable. This teaching gains additional strength from the case reported in the *Deutsch. Med. Woch.*, by Dr. Mosler. Ten days after the first appearance of cough, in a patient who would not eject, but always swallowed his sputa, diarrhoea and severe colic supervened, which proved fatal in eight days. The autopsy revealed tubercles in the lung and intestines. A recent attack of typhoid fever had, most likely, left the intestines weak.

Nerve Lesions in Skin Disease.

It would be a great stride in the progress of dermatology if we were able to trace a definite causative relation between nerve lesions and skin diseases. In *Virchow's Arch.*, Dr. Meyer relates a case of pemphigus, which commenced as a simple eczema. The patient died seven weeks from the commencement of the disease, diarrhoea being the most apparent cause. At the autopsy, the cutaneous blood-vessels were found obliterated by endarteritis, and the nerves showed extreme parenchymatous degeneration. While no symptom had been apparent, during life, of disease of the cord, marked scattered sclerosis was found. While he does not consider it settled, yet Dr. Meyer suggests that the vascular obliteration in the skin, by interfering with nutrition, may have rendered

it more susceptible to disease evoked by the condition of the nerve centre.

Salicylage.

This is the term applied to the practice resorted to in Paris of using salicylic acid as a preservative of food and drinks. The question of its injurious effects was recently referred by the government to Prof. Brouardel, who reports as follows: 1. The daily use of even the smallest dose of salicylic acid is unsafe, its innocuity not having been as yet demonstrated. 2. It is certainly dangerous for the subjects of lesions of the kidneys or of the liver from old age or by some degenerative process. 3. The prohibition of salicylage should be strictly maintained.

A Point in Diagnosis of Aneurism of the Basilar Artery.

MM. Hallopeau and Giraudeau relate a most interesting case in *L'Union Med.*, December 11, 1883. When the head was bent forward, respiration stopped in the stage of expiration, while the pulse, after beating regularly for some seconds, became gradually slower. When the head was thrown back, respiration was immediately re-established. It was supposed that the phenomena observed were due to the pons varolii having become compressed by the aneurism when the head was flexed, whereas during extension of the neck the artery would be elongated, and so the aneurism carried out of reach of the pons.

Kidney Disease of Pregnancy.

In a recent issue of the *Zietschrift für Geburtshülfe und Gynakologie*, Dr. Flaischlen concludes that it is due to a reflex anæmia of the kidneys excited by the gravid uterus. This anæmia leads to degenerative changes of the epithelium in the renal tubules. In consequence of these changes the excretion of urea becomes deficient. In some cases these changes come on during the latter half of pregnancy, and their evil consequences are then best averted by the induction of premature labor. Sometimes, on the other hand, they are produced by the uterine contractions of the process of labor itself.

Arrested Phthisis.

In view of the fearful mortality of this disease, it is encouraging to read of cases that have pursued a favorable course. In the *Boston M. and S. Jour.*, December 13, 1883, Dr. Bowditch reports a case of arrested phthisis. The patient lived to fifty-one, and had chronic pleurisy for two-thirds

of his life. Every few years crackling appeared under the clavicles. Although a microscope maker, he got as much walking as possible. There was no tubercle, but a general amyloid degeneration. The speaker would never give up a man who had the pluck to keep out of doors. Crepitation may last for twenty years.

Tuberculosis Conveyed by Food.

Two small children were fed with food that had been previously chewed by a phthisical mother. Soon ulcers appeared in the mouth, and they became emaciated. When death ensued, tuberculosis of the lungs, pleura, liver, spleen, kidneys, and lymphatic glands was found. It is worthy of note that while the mother's expectoration was scanty, the children maintained their health, but as soon as it became profuse they sickened. For some time before commencing to chew the food, the mother had suckled the children with impunity, but it must be remembered that the disease had not then advanced far. Hezerich reports this case in the *Bayerisches Artzl Intelligenz Blatt*, No. 26, 1883.

Cotton-Root Bark as a Substitute for Ergot.

Prochownick told a recent meeting of the German Gynecological Society (*Am. Jour. Obstet.*, January, 1884), that he had experimented with cotton-root bark because he thinks it desirable to find a substitute for ergot. The action of the drug, when employed during the last stages of the expulsive period, is inferior to that of ergot; but it produces no tetanic contractions. When given during the lying-in, the effect was very satisfactory. But the author was particularly pleased with it in gynecological cases, in hemorrhages continuing after the removal of remnants of abortion. In myomata, the metrorrhagias often diminished as early as after two months, but usually after three, and a reduction in the size of the tumor could also be demonstrated. Infusions of the fresh drug produce the best effects. The American fluid extract is likewise to be recommended. The drug is considerably cheaper than ergot. In reply to a question by Schatz, the author added that the agent can by no means fully supplant ergot.

CORRESPONDENCE.

The New Battery Solution.

EDS. MED. AND SURG. REPORTER:—

The subject of medical electricity is so important that any discussion about it will be sure to be read with interest by many physicians. This induces me to make a slight criticism just now.

I have read a communication in the current number of your journal on "A New Battery Solution," by Carl Seiler, M. D.

Now, although I do not profess to be "well versed in the chemistry of batteries," I am strongly of the opinion that Dr. Seiler's explanation of the reaction which takes place is incorrect. It is the *oxygen* of the water which enters into combination with the zinc and sulphuric acid—the *hydrogen* being evolved in the form of small bubbles which adhere to the surface of the carbon.

Again, "chromic acid is not a de-oxidizer, but a powerful oxidizing agent, giving off a part of its oxygen freely on slight provocation. The chromic acid in the solution acts as a carrier of oxygen; being decomposed by the action of the sulphuric acid, it parts with some of its oxygen (which at once unites with the free hydrogen to form water) and becomes the sesqui-sulphate of chromium.

GAMMA.

Poisoning by Turpeth Mineral.

EDS. MED. AND SURG. REPORTER:—

In the *Medical News* of December 22, 1883, is recorded a case of poisoning from turpeth mineral. I have had a very considerable experience in the use of this agent. As a rule, no emetic with which we are acquainted is so efficient in croup. It removes the laryngeal obstruction with a minimum amount of nausea and prostration, at the same time retarding and, in some cases, preventing the reformation of the membrane.

But, I am sorry to add, I know of one case of death from its use, and of another where the symptoms occasioned the gravest anxiety. The fatal case occurred during the last summer. A child of about a year was attacked with true croup. In addition to a general treatment, two powders, three grains each, of turpeth mineral were left. One was to be given if symptoms of suffocation developed. If this produced no vomiting in twenty minutes, the other powder was to be given. Neither came up. In about two hours great restlessness and diarrhoea came on. The bowels were moved every few minutes. Paroxysms of retching occurred frequently, but no vomiting. The stomach was not empty. Collapse gradually supervened, and in a few hours the child was dead.

Allow me to add, that no doubt can be thrown about this case. The drug came from the same bottle which had furnished the supply for at least a score of cases.

In the other case referred to, one dose of three grains was given. No emesis resulted. Diarrhoea, paroxysms of retching, and intense abdominal pain resulted, but passed off under treatment.

As for myself, I shall use no more turpeth mineral. I cannot feel justified in adopting means that may act favorably in ninety-nine cases, and yet kill the hundredth. It is important that others having had fatal results from this drug should publish the same. MEDICUS.

—Baltimore is to have a Polyclinic and Post-Graduate Medical School.

NEWS AND MISCELLANY.

A Nut for Anti-Vivisectionists.

In the course of an article on vivisection in the *New Orleans Medical and Surgical Journal*, December, 1883, the late Dr. J. Dickson Bruns thus eloquently raps the anti-vivisectionists of England:

"Are any of the members of the Royal Society for the Prevention of Cruelty to Animals, sportsmen? If so, have any of them ever had the curiosity to go through the covers with the game-keeper a day or two after *abattue*? How many birds with broken wings, dying by slow tortures, have they picked up? How many hares limping about with mangled limbs, some mortifying, all inflamed and exquisitely painful, have they seen? Or what excuse will be offered for the barbarous amusement of fishing?—have trout and gudgeons and worms no feelings! And if man may claim dominion over the beasts of the field, and may hunt and destroy them, not for food or for support, but for the gratification of taste, or the relaxation of mind, or exercise of body, or in mere wantonness, without reference to the pain he inflicts, shall he be denied the occasional use of them for the advancement of the noblest work that can engage his energies, even though that use involves at times a suffering almost equal to that which the rod, the gun, and the trap inflict?"

"Out! with such puling sentimentality—such mockery of the divine essence of charity! If the Royal Society want some real beneficent work to do, let it go down into the reeking slums of Westminster, where Lazarus lies in rags, almost at the gate of the queen's palace; or into the still fouler atmosphere of St. Giles and Whitechapel, poisoned with every moral as well as physical abomination; or into the starving districts of East London, and feed the hungry, and clothe the naked, and give light to those who sit in the shadow of death. 'Are not these of more value than many sparrows?'"

"When Christian Englishmen were blowing Sepoys from the mouths of cannon, and murdering Princes in the face of day, and sacking cities with sickening outrages, the Royal Society uttered no protest. Let her batter at the doors of Parliament until the hand is taken from the throat and the knee from the breast of prostrate India, every foot of whose soil has been won by rapine and murder, from the days of Clive to Campbell. India! which, when the British savage was running wild in his unwhewn forests, was possessed of a civilization whose magnificence is still attested in the ruins of her gorgeous architecture, the brilliant fragments of her letters, and the mutilated body of a religion whose moral code is only inferior to that which our Master himself taught. When it has purged the common weal of such enormities, we will be more willing to listen to it on the minor canons of the law."

Annual Mortality of Philadelphia.

The published statements of the Registry Bureau of the Health Department of this city show that for the year included between December 30, 1882, and December 29, 1883, the number of deaths in this city was 20,076, an increase of but

17 over the death list for 1882. Of this total for 1883, 10,711 were adults, and 9,365 were minors. Of the latter number 4,929 were boys and 4436 were girls, and of the total there were 10,223 males, and 9,854 females.

The record of nativities shows that 14,909 were natives of the United States, 4,500 were foreign born, and the birthplaces of 667 were unknown. The people of color numbered 1,112.

The principal causes of death were as follows: Alcoholism, 91; apoplexy, 340; Bright's disease, 307; cancer, 401; casualties, 293; cholera infantum, 877; cholera morbus, 28; congestion of the lungs, 247; consumption of the lungs, 2,787; convulsions, 802; croup, 500; debility, 459; diphtheria, 996; heart disease, 709; malarial fever, 75; scarlet fever, 561; typhoid fever, 579; whooping-cough, 85; inflammation of the lungs, 1,282; inflammation of the stomach and bowels, 509; inanition, 414; marasmus, 816; old age, 767; paralysis, 389; smallpox, 173; teething, 22; and tetanus, 36. In addition to these there were 60 deaths from insanity, 17 murders, and 94 deaths were classified as suicides. Of the suicides, there were by hanging, 25; shooting, 22; poison, 25; drowning, 5; cutting of the throat, 16; and jumping from a window, 1.

Of the total there were under 1 year, 4201; from 1 to 2, 1874; from 2 to 5, 1832; from 5 to ten, 1037; from 10 to 15, 350; from 15 to 20, 561; from 20 to 30, 2044; from 30 to 40, 1816; from 40 to 50, 1643; from 50 to 60, 1553; from 60 to 70, 1,475; from 70 to 80, 1343; from 80 to 90, 719; from 90 to 100, 123; and from 100 to 120, 6.

Longevity of Medical Men.

The following eminent physicians and surgeons died last year in England at ages varying from 78 to 96: John Flint South, F. R. C. S., late President of the Royal College of Surgeons of England, and Surgeon to St. Thomas's Hospital, 85; George Samuel Jenks, M. D., Edinburgh, F. R. C. P., London, 93—he served in the Peninsula from 1812 to the end of the war in 1814, and at Waterloo; Price Blackwood Hallows, F. R. C. S., England, 81; Sir Robert Christison, Bart., M. D., D. C. L., LL.D., one of her Majesty's Physicians in Ordinary, Scotland, 85; John Francis De Grave, M. R. C. P., late Master of the Society of Apothecaries, 92; John Lonsdale Minshull, F. R. C. S., England, 81; George Macilwaine, F. R. C. S., England, 86; Sir James Alderson, M. D. Oxon, D. C. L., F. R. S., Physician Extraordinary to the Queen, and late President of the Royal College of Physicians, London, 87; Henry John Gore, F. R. C. S., England, 85; Staff Surgeon William St. George Davies, R. N., 96—he served as Acting Surgeon in the *Norge* at the bombardment of Copenhagen under Admiral Gambier and Lord Cathcart in 1807, and was in all probability the very last survivor of that engagement; Henry Bell, M. D., 85; George Gulliver, F. R. S., F. R. C. S., late Surgeon Royal Horse Guards, 79; A. E. Blest, M. D., Edinburgh, Indian Army, 85; Staff Surgeon Cotton, 87; Edward Greatrex, F. R. C. S., late Surgeon Coldstream Guards, 83; Edward Doubleday, F. R. C. S., 84; John Hawthorn, 86; Sir Thomas Watson, Bart., M. D., D. C. L., F. R. S., Physician in Ordinary to the Queen, and a former

President of the Royal College of Physicians, London, 90; Inspector-General Cross, R. N., 78; James Arthur Wilson, M. D., F. R. S., Senior Fellow of the Royal College of Physicians, 88.

Great Men and Small Heads.

The *Athenæum* says: "It is usually supposed that men of great intellectual powers have large and massive heads. But this theory, which Dr. Gilbert, physician to Queen Elizabeth, was the first to suggest, is not borne out by facts. An examination of busts, pictures, medallions, intaglios, etc., of the world's famous celebrities, almost tends the other way. In the earlier paintings, it is true, men are distinguished by their large heads; but this is attributable to the painters, who agreed with the general opinion, and wished to flatter their sitters. A receding forehead is mostly condemned. Nevertheless, this feature is found in Alexander the Great, and to a lesser degree in Julius Cæsar. The head of Frederick the Great receded dreadfully. Other great men have had positively small heads. Lord Byron's was 'remarkably small,' as were those of Lord Bacon and Cosmo di Medici. Men of genius of ancient times have only what may be called an ordinary or every-day forehead, and Herodotus, Alcibiades, Plato, Aristotle, and Epicurus, among many others, are mentioned as instances. Some are even low-browed, as Burton, the author of 'The Anatomy of Melancholy;' Sir Thomas Browne, and Dürer. The average forehead of the Greek sculptures in the frieze from the Parthenon is, we are told, 'lower, if anything, than what is seen in modern foreheads.' The gods themselves are represented with 'ordinary, if not low brows.' Thus it appears that the popular notion on the matter is erroneous, and that there may be great men without big heads."

An Improved Way to Dispose of Used-up Animals.

Mr. George Lam Fox, of London, has devised the apparatus: The animal to be killed, first has the top of its head and its feet and its legs wetted with salt water. It is then led into a stall and made to stand upon an iron plate connected with the negative pole of a condenser of a capacity of about one hundred microfarads. The operator then touches the animal's head with the positive pole, and it falls dead. The death is believed to be painless, because physiologists have demonstrated that a nervous vibration cannot be communicated to the brain in less than a tenth of a second, and another tenth of a second must elapse before a sensation can result from the vibration thus communicated. One-fifth of a second must, therefore, necessarily intervene between the actual infliction of an injury and the experience of pain from it. But the flash from such an apparatus as has been described, presumably paralyzes every fragment of a nerve in man or beast in something like a hundred-thousandth part of a second. It is said for about two thousand five hundred dollars such an electrical apparatus as is here alluded to may be fitted up in any stable or outhouse, and that it will kill as rapidly as animals can be placed in position and taken away again.

The Medical Society of the State of Pennsylvania.

The annual meeting of this Society will be held at Philadelphia on May 14, 15, and 16, 1884, in the Assembly Room of the Union League, Broad and Walnut streets. The President's reception and the entertainment by the Philadelphia County Medical Society will be held on the evening of May 14, at the Pennsylvania Academy of the Fine Arts, Broad and Arch streets.

The By-Laws require the programme of the meeting to be printed and distributed at least one month before the date of the meeting, and no voluntary paper is allowed to occupy more than twenty minutes in its reading.

Notice is hereby given that all those who wish to present papers should send the full title and a short abstract of the same to the Committee on Arrangements on or before March 1, 1884, in order that a varied and attractive programme may be prepared.

No paper will be selected for a position upon the programme of the meeting unless an abstract has previously been seen by the committee.

By order of the Committee.

JOHN B. ROBERTS, *Chairman*,
1118 Arch street, Philadelphia.

Insanity in France.

Recent reports show an increase in the number of inmates in the insane asylums in France. There are 103 asylums, of which 61 are private; 14 are for women only, and 9 for men only. In 1868 the number of inmates was 34,000, to-day it is nearly 60,000. This increase may be accounted for partly by referring to the fact that the attention given to mental disorders is much stricter than formerly. The authority from which these figures are taken also states that men are cured on an average in 276 days, and women in 295. The stay varies according to the cause of the disease, lasting 287 days in cases of simple insanity, 250 days for paralytic insanity, 289 days for senile insanity, and 398 days for idiocy and cretinism.

The Advantage of Koumiss.

In the course of an article by Adolf G. Vogeler, in the *Chicago Druggist*, the following occurs:

The reasons why good koumiss is so well borne by a weak stomach, and why it is so nourishing, are shortly these: The casein is so minutely divided that it is most readily attacked by the digestive fluids. Appetite is improved by the stimulating influence of carbonic acid on the mucous lining of the stomach.

Lactic acid being an essential constituent of the gastric fluid, the stomach is relieved of part of its work by the presence of that body in koumiss. And finally, the small percentage of alcohol increases the gastric secretions, and by increasing the force and frequency of the pulse, the muscular system is built up by the more generous supply of life-giving blood.

Personal.

—Dr. Wm. Thomson, of this city, has changed his residence from 1508 Locust, to 1426 Walnut street.

—Thomas Holloway, the millionaire manufac-

turer of pills, whose immense warehouse on Oxford street is one of the sights of London, is dead, aged eighty-four years. One of his latest acts was a gift of \$500,000 to the hospitals of London.

Items.

—A baked bean lodged in the vermiform appendix caused fatal inflammation in a resident of Lynn, Mass.

—Dr. John Beattie Crozier (*Lancet*, November 17, 1883), reports good results from venesection in uræmic coma.

—The *Lancet*, November 17, 1883, contains a report of a case where a cystic polypus of the rectum complicated parturition.

—In the *Lancet*, November 24, 1883, Mr. W. Collier reports a case of angina pectoris much benefited by nitrite of sodium.

—An interesting work treating of the history of the Salpêtrière from 1656 to 1790 has recently been published in Paris.

—In the *Boston Med. and Surg. Jour.*, December 6, 1883, Dr. D. D. Gilbert reports a case of "tubal gestation, with rupture and sudden death."

—The New England railroads have killed in the past year, two hundred and twenty-one persons, and injured five hundred and thirty-five.

—In the *Brit. Med. Jour.*, December 1, 1883, Mr. Startin reports a case of elephantiasis of the scrotum, which he considered to be due to an injury.

—Major J. S. Billings, of the Medical Department of the Army, has been placed in charge of the Medical Museum in Washington.—*New York Tribune*.

—This is the time to try whether the coating of windows with a thin film of glycerin—as recommended by the *Scientific American*—will prevent frosting in cold weather.

—According to Dr. Billings, it appears that of one million colored infants born (in Baltimore) one-half will have perished before attaining the age of two years.

—It is announced that the late Dr. Marion Sims has left a sketch, entitled "Lydia McKay and Colonel Tarleton," which will appear in the February *Harper*.

—Dr. Frank O. Stockton, of Newark, N. J., has been elected to the professorship of diseases of the nose and throat in the College of Physicians and Surgeons of Chicago.

—In the *Medical Times and Gazette*, December 15, 1883, Dr. Arthur G. Blomfield reports a case of fracture of fourth cervical vertebra, with immediate paraplegia and death.

—In the *Glasgow Med. Jour.*, December, 1883, Dr. John McDonald reports a case of severe cerebral concussion, in which large doses of the bromide of potassium averted death.

—In the *New Orleans Medical and Surgical Journal*, December 1883, Dr. J. J. Burroughs reports a case of Cæsarian section, with successful delivery of a living fetus; the mother died.

—A *patent medicine* "testimonial" says: "Five

doctors and gallons of medicine failed to cure me." He ought to be thankful they didn't kill him. It was a narrow escape.—*Norristown Herald*.

—According to the Chinese, the flesh of a black rooster strengthens the bowels, the tendons control deafness, the intestines cure incontinence of urine, and the blood of the comb increases the milk of nursing women.

—In a communication to the Académie des Sciences, M. Krechel has drawn attention to another method of adulteration of milk, which consists in adding to it an aqueous solution of commercial glucose having the same density.

—A case in which the middle phalanges of the index, middle, and ring fingers of the left hand were completely dislocated on to the dorsa of the corresponding proximal phalanges, is recorded in a recent number of the *France Médicale*.

—The whistle of a locomotive is heard 3,300 yards, the noise of a train 2,800 yards, the report of a musket and the bark of a dog 1,800 yards, the roll of a drum 1,600 yards, the croak of a frog 900 yards, and a cricket's chirp 800 yards.

—In the *Annales de la Société Médicale de Gand*, Drs. Van der Mursch and De Visscher describe the symptoms during life, and the results of the necropsy, met with in a child two years of age, who died in five hours from swallowing half the contents of a bottle containing 150 grains of nitrobenzine, procured by its mother for making pomade.

QUERIES AND REPLIES.

EDS. MED. AND SURG. REP.:—

I have heard that china painting is injurious to the health. Do you think it is, and why do doctors say so?

LADY READER.

Ans.—It is alleged to be so, on account of the turpentine and lavender oil used. The fumes of these ingredients certainly disagree seriously with some people. But we regard them as exceptions, and do not believe that in most cases any danger attends the practice of this minor art.

—Is the certificate issued, upon examination, by the State Board of Health (Illinois for example) valid in other States where an examining board exists? I think it should not be ignored any more than a diploma issued by a "recognized" (viz., American Medical College Association) College of Medicine and Surgery.

J. T.

Ans.—We doubt if it would be received in another State but no test case has come to our knowledge.

—*Chemist, N. Y.*—We have no faith in anonymous analyses of quinine pills or anything else. Medical journals which publish such usually have "an axe to grind."

MARRIAGES.

ARMSTRONG—COOLBAUGH.—At the home of the bride, in Wysox, December 25, 1883, by the Rev. Hallock Armstrong, of Aspinwall, Addison Alexander Armstrong, M. D., of Austinville, and Miss Hattie W. Coolbaugh, all of Bradford county, Pa.

DEATHS.

URQUHART.—In this city, January 6, 1884, David C. Urquhart, M. D., in the seventy-second year of his age.

THE MEDICAL AND SURGICAL REPORTER.

No. 1404.]

PHILADELPHIA, JANUARY 26, 1884.

ORIGINAL DEPARTMENT.

COMMUNICATIONS.

WHAT IS MEANT BY NERVOUS PROSTRATION?*

BY ROBERTS BARTHOLOW, M. D., LL. D.,

Professor of Materia Medica and General Therapeutics, in
the Jefferson Medical College of Philadelphia.

The popular conception of the condition now known as "nervous prostration" is a state of debility, in which nervous derangements predominate. A man actively engaged in business or in public life, presently finds himself unequal to his daily tasks; he suffers odd sensations in his head; his digestion is disordered; he is weak; wakefulness, mental depression, and a thousand and one new sensations of strange character and fearful portent, are superadded. The unfortunate subject of these ills now recoils from his work, gives himself up to the consideration of his symptoms, and relaxes his hold on the interests and occupations of his life. All the world declares that he has "nervous prostration," and this explanation satisfies. Physicians say "neurasthenia" or "hypochondria," according to their habits of mind or to their training. Sometimes this condition is called the "American Disease." Indeed, there is a general notion, widely prevalent, that neurasthenia is a peculiarly American malady. The late Dr. Beard was the apostle of this dispensation, and he not only was noisy and persistent in his advocacy of that view, but claimed, indeed, to have first clearly defined neurasthenia, and to have classified under this designation the numerous symptoms pertaining thereto. If we cannot

admit Dr. Beard's claim in its entirety, if we experience repulsion at his tremendous, but unconscious egotism, we are still compelled to acknowledge that his work in this connection is the most important that has appeared. He was peculiarly fitted to differentiate this malady by reason of the quickness and acuteness of his intellect, his power of analysis in its subtlest aspects, and his far-reaching, his omnivorous faculty for related facts.

The term *neurasthenia*, advocated by Beard, is by no means of recent origin. The corresponding French word, used in the same sense as we now employ it, has been a stock word of French neurological medicine for fifty years. Under the terms spinal irritation, hysteria, hypochondriasis, the nervous state, etc., symptoms of the same character as those now included in the word neurasthenia have been described. Besides the general state, similar derangements of functions of particular organs have been separately considered, as palpitation of the heart, headache, flatulence, impotence, etc. In the word neurasthenia—popularly, nervous prostration—the whole morbid complexus is included. The question I have to consider is whether this is a real, a substantive disorder. Are the notions now entertained about it founded on a true conception of the condition?

I need not enlarge on the importance of a correct understanding of a morbid state, which is supposed to be due to the conditions of modern, especially of American life. Without stopping now to question the soundness of the prevailing doctrine, I will place before you the clinical history of two cases, representatives of the two types of neurasthenia. These may be designated re-

*Read before the Philadelphia County Medical Society.

spectively as the *congestive* and the *anæmic* varieties. The latter are greatly more numerous, but the former are not uncommon, as Beard admits.

CASE I.—THE CONGESTIVE TYPE.

Mr. —, æt. 44, president of one of the largest railroad corporations of the West. He is now a robust man, five feet ten inches in height, 196 pounds in weight, and has a very dark complexion, his type of constitution being the so-called bilio-nervo-sanguineous. Beginning his career at an early age in a subordinate position, he has, by the force of a superior intellect and of a physique that no labor could subdue, risen to the highest office, and now controls vast interests. Ambitious, enterprising, resolute, he has carried these faculties into all his work, and has shrunk from no task, however severe—from no responsibility, however onerous. As he has risen in position, social engagements have also added to his burdens. His mode of life has changed to some extent. His habits have become more sedentary, although diversified by frequent railroad journeys; the pleasures of the table, including wine-drinking and late suppers, have been more and more indulged in: excessive smoking has been added to these indulgences; and thus, whilst his physical powers have been slowly impaired by bad hygiene, the demands on his mental powers have increased. Extensive interests, uncertain, often precarious, business arrangements, and the incessant watchfulness required when vast combinations may be wrecked through failure at any point, demand the highest use of every faculty; and thus to work is added worry.

Three years ago Mr. — observed that he was not feeling well, and that he could not work as before. He became dull, especially after meals, had a constant headache, dizziness and throbbing of the temples; he applied his mind with difficulty, and all of the head symptoms were increased by the efforts made; he had a good, rather a keen, appetite; a heavily-coated tongue, flatulence, constipation, and some colic pains. The bladder was rather irritable, especially at night; sexual inclination had declined with lessened power, and various ill-defined, but annoying sensations were felt about the penis, scrotum, and perineum. During the first year the symptoms increased; the attacks of vertigo were sometimes very severe, so that he had to support himself for a moment to save him from falling. On several occasions he became very much dazed, even lost consciousness momentarily, and once wandered some distance from the proper route he was taking. Anomalous sensations of creeping and crawl-

ing, coldness and tingling, and often a burning heat, were felt in the scalp; sudden detonation in the centre of the head apparently; buzzing and singing in the ears, and very constant headache, were also experienced. In the extremities, the tongue, and the genitals, there were felt peculiar tingling, numbness, coldness, creeping, and similar sensations. During the whole time of the existence of his symptoms, Mr. — suffered from depression of spirits, a deep melancholy in fact, and he lived in constant apprehension of failure of mind.

Physicians whom he consulted in the West, located the malady in the brain, diagnosed cerebral hyperæmia, the prelude to softening.

When Mr. — came to see me, sixteen months ago, the symptoms just detailed continued, and were rather increased than diminished. The objective examination furnished the following details:

His face is full, the eyelids puffy, and the lower lid swollen into a bag; the conjunctivæ are injected, the sclerotic muddy, and the pupil sluggish in movement. On ophthalmoscopic examination, the fundus is seen to be injected, small vessels prominent, veins swollen. There is no optical defect except that due to his age. The membrana tympani is also rather deeply red, and vessels too small to be seen under ordinary circumstances are now in view. Hearing is unaffected. Motility, sensibility—the tactile, pain, and temperature senses—are unaffected; and the reflexes remain normal, although probably a little sluggish. The electrical reactions are normal.

His tongue is heavily coated, the breath foul. His appetite is good, but a sense of fullness at the epigastrium persists for several hours after meals; acidity and eructations of rather foul gas now and then occur. The stools have the normal appearance—consistence, color, and odor. The urine is copious, acid, specific gravity rather high (1025 to 1030), and there are traces of sugar, as is usual under such circumstances.

The action of the heart is good, the pulse regular, the tension of the vessels rather high. The respiratory movements and murmurs are normal. The area of hepatic dullness is rather enlarged, and the splenic dullness seems also to be increased.

Subjectively the following symptoms are experienced: Various strange sensations in the scalp; a persistent headache; blurred vision at times; vertiginous feelings occurring irregularly and of varying severity; despondency, vague apprehensions; fear of places, especially of crowded assem-

blages; difficulty of deciding questions, very trivial or otherwise, in place of former promptness; impaired memory, for persons, names, and things.

Notwithstanding this extended list of symptoms, Mr. — did not have an ill look, but, on the contrary, on superficial examination, appeared to be robust. To him and to his immediate family the situation seemed in a high degree alarming. The surrender of his position and his business interests was regarded as imminent. To the apprehension awakened by his head symptoms was added the diagnosis of cerebral congestion, and hence the profound melancholy into which he was plunged.

Commentary.—My conclusion was that the disturbances in the functions of the brain and nervous system were secondary to derangement of the assimilative processes—of the primary and secondary assimilation—and that to the functional disorder thus caused are added the effects of introspection, and the realization by the centres of conscious impressions to an unusual extent, of ordinary peripheral excitations. My reasons for coming to this conclusion will appear hereafter. The remedies consisted in a careful regulation of the diet, in baths, exercise, in a reduction of the hours devoted to work, but not the cessation of work; in the use of a laxative quantity of sodium phosphate daily, and in the administration of the aqueous extract of ergot, with the chloride of gold and sodium, and a minute quantity of bichloride of mercury. If time and space would allow, the details of the hygienic management—so important in these cases—could very profitably, I think, occupy our attention. But I must pass on to the next case.

CASE II.—THE ANÆMIC TYPE.

Mr. —, æt. 57; a lawyer by profession. His type of somatic constitution is *nervo-sanguine*; weight, 145; height 5 feet nine inches. He has immense mental energy, extraordinary quickness of perception, a capital logical and critical faculty, and fine oratorical powers. These native abilities, conjoined with extensive cultivation, soon placed him amongst the foremost men at the bar of the city where he practiced, and have long maintained him in that position. For many years he has been a dyspeptic, and suffered much from eructations of gas, from acidity and flatulence. At times—months, even years intervening—he has experienced very severe seizures, accompanied by extreme mental depression, alternating with an extreme mental exaltation. During the past five years he has had two attacks of gout, neither

severe nor protracted. During the whole course of his professional life he has sustained no reverses, encountered no other anxieties than those of a successful lawyer, and has been rather singularly free, indeed, from the worries of life. Receiving last summer the nomination as a candidate to an important office, this cultivated gentleman, scholar, and lawyer, this man of nice tastes and high tone, entered on a canvass marked by vituperation and slander to an unusual extent. About the same time some business interests became entangled, and caused no little worry. During the campaign he visited some malarious districts, and spoke several times at night in the open air. A speaker of great readiness and power, he never suffered from any considerable fatigue after public speaking, and hence he was now surprised to find himself exceedingly tired even after a brief effort. He began to have drenching night-sweats, lost his appetite, grew weak, and was compelled to return home. It was then ascertained that he had malarial fever, and he was treated accordingly. But at this time, and subsequently, symptoms not necessarily of malarial origin appeared. He became frightfully dyspeptic, had enormous eructations of gas, and very considerable flatulence; his arms and legs had a numb feeling, attended with “pins and needles;” he walked with some difficulty, partly because of weakness; he was somnolent and slept a good deal, and his spirits were extremely depressed, especially on awaking in the morning. During these periods of depression he was so overwhelmed with despondency that he was apprehensive he would lose his self-control entirely.

When he placed himself under my charge, he had still a slight daily paroxysm of fever, the exacerbation occurring in the morning, but this disappeared in a few days under the action of some efficient doses of quinine. He was very weak, pallid, and emaciated, and slept a good deal of the time. He had no headache; his vision was rather dull, and ideas and speech slow. Every morning on awaking he was profoundly melancholic, and all the annoyances which the campaign had developed were gone over in his mind. He could talk of nothing else, think of nothing else, than his ill feelings and the disagreeable political and personal slanders of which he had been made the victim. He complained much of the numbness of his hands, of weakness in the limbs; and he talked incessantly of his depressed feelings. The bladder became irritable, and he was compelled to rise every two or three hours, during the night, the urine being acid, and depositing heavily of

uric acid. Presently the somnolence was displaced by insomnia, and he slept less and less, and rose in the morning haggard, exhausted, and horribly nervous and depressed. Ordinary hypnotics proved unequal to the effort to force sleep, and increasing doses of chloral became necessary. His mental activity, heretofore so remarkable, declined, and the effort to force his mind to the performance of any work, such as letter-writing, caused a sensation of fatigue. He also became undecided, even in small matters, ceased to have any inclination to go out and mingle with the public, and grew more and more averse to political movements. He reached a point finally when to meet strangers caused him great distress, excited the circulation, and induced a cold sweat.

As it became indispensable that he should resume the canvass, he made a strong effort, and notwithstanding the fatigue, mental and moral depression and exposure of public speaking, handshaking, and other matters of political expediency, he actually improved somewhat. The insomnia, irritable bladder, and hypochondriasis, however, continued, but to a less degree. In a few weeks, by means chiefly hygienical, I succeeded in stopping the chloral; natural sleep was resumed, although it remained somewhat fitful. Suitable dietetic regulations, baths, exercise and medicines, *pro re nata*, removed, or at least greatly modified, the principal symptoms. Two weeks at Atlantic City accomplished no little good, and when he returned to Philadelphia last week he appeared to be nearly his old self.

Commentary.—In this case we have exhibited that complexus of symptoms entitled neurasthenia or nervous prostration in its anæmic form, produced by several factors—moral and somatic. The moral were very influential, but unless the conditions producing bodily depression had occurred, the former causes could hardly have effected such results. Long-standing dyspepsia had prepared the way; malarial intoxication and fatigue contributed an important series of changes, and upon this weakened bodily state were precipitated crushing moral influences.

These cases, whose histories I have just read, are typical—each is the representative of a group. The causes are complex; the effects are not limited to one organ, or set of organs, but involve the system in general. To name this malady from the disturbance in one system seems to me an error, unless the definition is sufficiently elastic to include all the functions affected. Neurasthenia names one, only, of the parts involved. To entitle this the “American Disease,” is a strange

misnomer. It might with more propriety be called the “French Disease,” for a condition known as “the nervous state,” as “nervism,” as “neurasthenia” and similar terms, has been recognized and frequently described by French writers from an early period in this century. In France have existed the causes in the most influential form. The frequent political convulsions, the exacting social life of the great cities, and the harassing struggle for existence inseparable from the state of the great mass of the population, induce—if any mere external conditions can—that which is called nervous exhaustion. There are two factors supposed to be especially influential in this country—work, and our exciting political and social life. I believe that the effect of these is greatly overrated.

The brain, of all the organs of the body, illustrates, in the most perfect manner, that which has been happily styled “the principle of least action.” That is, to execute given tasks, it expends the least possible force; or, to express the same idea in another form, its work is done with ease, with the minimum of effort. Given a certain amount of repose—sleep—and supplied with proper nutriment—healthy blood—the brain will do its allotted work continuously during its working—the waking—hours. So far from being injured by severe labor carried on under normal conditions, the brain is improved by it. Mental activity, like muscular exercise, keeps the brain in a healthy state. When, therefore, a man says he is suffering from the effects of mental overwork, I want to know what his vices are. Worry may be one of these. Worry is exhausting. The worries of life do infinitely more harm than the work of life, how onerous soever it may be. The cases I have just read illustrate this.

I deny that life is more exciting on this side of the Atlantic. The one prize of life is money, and to get possession of it is the supreme purpose, to the attainment of which every energy is put forth. Is it less so elsewhere? Who are the peoples that despise money, and make no effort to obtain it? Here life is less exciting, because our political condition is stable, and but comparatively little exertion is required to secure a comfortable subsistence. I am speaking now of the mass of the population, and not of the few consumed by the ambition for political and social distinction, or led by a pitiless greed. It is the very ease and luxury of our American life that cause mischief. It is the indulgence in eating and drinking, the abuse of alcohol and tobacco, sexual excesses, sedentary habits, and too lux-

urions lives generally, that induce the state of the system called nervous exhaustion. If I had time, each of these should be considered, in relation to this subject. In the first case I narrated, the pleasures of the table and disordered assimilative functions caused the trouble. In the second case, dyspepsia, malarial toxæmia, and unusual fatigue, were the pathogenic factors. In both, the effects of these causes were increased by moral influences—in one, the anxieties involved in vast business enterprises; in the other, the excitement of a hot political contest. These moral causes would have had no injurious effect, had not the somatic conditions been unfavorable.

I come now to the most difficult part of my subject. I have to answer this important question: Why are the somatic derangements caused by the conditions referred to, in some cases accompanied by the mental and nervous symptoms which belong to neurasthenia? Why do some objects with indigestion and assimilative disorders, or with the results of dyspepsia and malaria, suffer from derangements of the mental and nervous functions, and not others? I might here take refuge behind an accepted generalization, and say that the presence or absence of the neurotic type of constitution explained the difference in the result. There is aptness in this explanation, but it is not entirely adequate. There is a mental condition of great importance, and unless we comprehend this, we fail to realize all the possibilities of the nervous side of these cases. I, however, barely hint at the main points, under these circumstances. Besides, I wish to avoid a too metaphysical discussion of the subject.

In the conduct of life every man who has a position to make or to maintain, exerts a certain moral force to hold himself up to his work. Some men are so happily constituted that they are quite unconscious of the effort and stand in front, serenely confident. Others are all the time laboring; they feel it and know it, and like the soldiers of Thomas's corps at the battle of Chickamauga, sorely pressed, now and then looked back, to see whether their grim and resolute commander was still behind them with his invincible courage, men conscious of the effort making to keep up, need but little excuse to surrender themselves to their sensations. At the present time nervous prostration is much feared; its symptomatology is a common subject of discussion; and hence, familiar with its character, a man who is arrested in his career by some of the ailments supposed to belong to it, his imagination readily supplies the rest. When a man begins the study of his bodily

sensations, having a certain model in his mind, he has little difficulty in filling out the details. All the world knows that when the attention is strongly fixed on an organ of the body, functional disturbances of it ensue, and finally structural changes may be induced. No part of the body is without sensation, even in health. To perceive these sensations the attention needs to be withdrawn from external things, and concentrated on the part. Thus it is when the subject of neurasthenia pursues his introspection; he becomes conscious of numerous sensations, which, because now felt for the first time, are new. Under these circumstances, also, the seat of conscious impressions becomes more acutely perceptive, Suggestion adds its quota of symptoms.

To the indefinite and multiplying nervous symptoms developing thus subjectively, must be added the reflex. Headache, vertigo, *tinnitus aurium*, amaurosis, diplopia, hallucinations and illusions, defects of speech, paralysis, are reflex symptoms on the part of the brain; palpitation, intermittent pulse, angina pectoris, laryngismus stridulus, asthma, are amongst the reflexes of the respiratory organs and heart; neuralgia, anæsthesia, and other disorders of the sensory nerves, and local paralyses, affections of the motor nerves, included amongst the nerve reflexes, may all be dependent on reflex excitations proceeding from the stomach. Indeed, there is no symptom in Beard's catalogue of those belonging to neurasthenia that may not be due to merely reflex influences having their initial seat in the digestive apparatus. It follows that the term neurasthenia, or its common equivalent, nervous prostration, is either inadequate, or it expresses too much: inadequate if the complex of symptoms includes the functional disturbances of all the organs affected—expresses too much if the malady is a merely nervous one.

In reply to the question: "What is meant by nervous prostration?" I respond, "a disease usually functional, situated in one or more organs, during the course of which reflex disturbances of the brain occur, and numerous subjective sensations in all parts of the body are realized by the consciousness."

I deny that neurasthenia is a primary nervous affection, or that it is a substantive disease. I hold that it is symptomatic and secondary.

This conception fixed in the mind, the treatment of neurasthenia is successful or unsuccessful according to the measure of our skill in localizing the initial disturbance, and in addressing our remedies to that, as well as to the general state.

SOME POINTS CONCERNING SANGUIS BOVINUS EXSICCATUS (DESICCATED BLOOD).

BY F. E. STEWART, M. D., PH. G.,
Of Philadelphia.

I see that the fifteenth edition of the United States Dispensatory, recently published, gives me credit for the introduction of sanguis bovinus exsiccatus (desiccated blood), as a Method of administering iron. As that is only one of its uses, and by no means the principal one, I beg leave to call attention to the following brief summary of what I consider to be the true position of this valuable agent in therapeutics.

Sanguis bovinus exsiccatus is a concentrated nutritive tonic prepared directly from the blood of bullocks, by simply drying it at a low temperature, to prevent the albumen from coagulating by the heat, and in shallow pans. The product, when so prepared, is in the form of thin scales somewhat resembling the scaly salts of the pharmacopœia. The blood may be prevented from clotting by stirring it before drying, and removing the small portion of fibrin that attaches itself to the stirring rod, or by adding a small portion of acid to the blood before submitting it to the desiccating process.

The article thus prepared contains all the elements of the blood, and in a form for easy assimilation; but, more than this, it contains potentially all that vast amount of energy required to raise blood from the plane of elements and of chemical compounds to that of animal life. It is, therefore, not only an agent for building and repairing tissues, but is, at the same time, a fuel, and its combustion in the system is capable of generating a large amount of vital energy for carrying on the vital processes.

Furthermore, this article contains iron in that peculiar combination found in the blood, and this form, so far as known, can only be manufactured by vital chemistry. The important relation that iron bears to the health of the red blood corpuscle, and the special relations borne by the red corpuscle to respiration and to the nervous system, are well known, and, together with the facts already stated, will probably account for the great benefit following the administration of desiccated blood, even in quantities too small for the credit to be entirely due to the albumen which it contains.

Indications for Use.—Desiccated blood has been used with benefit in wasting diseases; in various cachexia, such as scrofula, consumption, and syphilis; in anæmia and chlorosis; in atonic dyspepsia; after hemorrhages and exhaustive discharges; in the height of the fever process to

supply the combustion of tissues incident thereto, and to forestall a prostrated condition endangering life from exhaustion; in convalescence from fevers; and as a "building up" measure in surgical cases before operations, and after operations to hasten the reparative process. It is indicated in all cases where it is desirable to give iron, but more especially whenever the problem is to give food.

If quickly dried, this product is odorless, and almost entirely devoid of unpleasant taste. It may be administered either by the mouth, or by the rectum; preferably, however, by the former method. When administered by the mouth, it may be prescribed in combination with glycerine, with glycerine and brandy, or simply in solution with water. In either case the blood should be first dissolved in water. A very good formula, suggested to me by Dr. Andrew H. Smith, of New York, is the following:

R. Sangu. bov. exsiccatus,	℥vj.
Aquæ,	fl. ℥iv.
Misce ft. sol.	
Adde spts. vin. gal. et glycerinæ	
ana ana.,	℥j.
S.—Tablespoonful three or four times daily.	

In fever cases, when the temperature is high, I am in the habit of giving a teaspoonful, or more, as the stomach will bear it, every hour, carefully watching the dejections to see that it is all assimilated; and its use in this manner has been followed, in a number of cases, by the most gratifying results. In some cases, however, it is not assimilated, and stains the dejections black. In such instances, the addition of pepsin will usually remove the difficulty. As a disguise to the taste, I have been in the habit of employing some of the essential oils, a few drops of which will answer the requirements.

With regard to the use of blood per rectum, I have found that in some cases it is readily absorbed, and in other cases absorption does not take place. The reason for this I have never been able to ascertain. Pepsin should always be added to the solution when difficulty of this kind is experienced.

A point or two with regard to making a solution of desiccated blood. When preparing an aqueous solution, *never pour the water on the scales; always pour the scales in the water.* This point cannot be too strongly insisted upon. Then stir with a glass rod or spatula until dissolved, taking care to prevent the agglomeration of the scales into a mass. Again, always use *cold* water in forming the solution. Blood contains a large proportion of albumen. In fact, the dry blood is almost all albu-

men, and albumen coagulates at a temperature of 160° F. There is about as much sense in attempting to dissolve dry blood in hot water as to attempt the solution of an egg in the same medium. In either case the albumen coagulates and becomes hard. If a little more attention were paid to this well-known fact, we would hear less of those displays of stupid ignorance on the part of certain individuals, who have attempted to dissolve desiccated blood in boiling water.

For rectal use, the solution should be gently warmed before injecting, taking care not to raise it to a sufficient temperature to coagulate the albumen.

SOME OF THE USES OF ELASTIC PRESSURE.

BY J. S. MANNING, M. D.,
Of Manchester, Ky.

The great value of the elastic bandage became widely known to the profession through the labors of Esmarch. By the employment of graduated pressure, he was enabled to drive the blood from an extremity to the rest of the body, thereby enabling the operator to see his work and accomplish his undertaking thoroughly. There was now no longer need of undue haste, because the vital fluid was not ebbing away, as had been the case after the ordinary methods, and the surgeon might see as well as feel in his deeper dissections.

With the assistance of the elastic bandage, operations were successfully accomplished that without it had been considered impossible.

It is with a view of extending the knowledge of the usefulness of elastic pressure as a therapeutic agent that this article is penned. If a brother physician should find anything practical herein, whereby he might relieve suffering humanity of some of the many ills that weigh it down, the object of its mission will have been fully accomplished.

The uses of elastic pressure in varicose veins, and in aneurisms and chronic ulcers, are familiar to the reading part of the profession. Of course, no one undertakes to treat these disorders without resorting to pressure as the essential element of success. A far more extended use of graduated pressure should be adopted by the profession. In all incipient inflammations, judicious pressure, wherever available, would be of much benefit. To particularize: An incipient whitlow upon one of the digits may be aborted by using a narrow bandage of elastic tape or pure rubber. Apply the bandage with moderate and equable pressure from the distal extremity till it reaches

the proximal side of the seat of the whitlow. The pressure should not be sufficient to drive all the blood out of the extremity, but enough to relieve congestion and reduce the swelling. Now, if stasis and necrosis of tissue have not already taken place, the inflammatory products will be absorbed, and all will be well again. The principle of its action is simply that pressure produces absorption, first of inorganized products or adventitious growths; and second, of healthy tissues themselves, producing atrophy.

Again, the principle above enunciated may be employed in the treatment during the early stage of inflammations of the joints, as wrist, elbow, ankle, or knee joints, whether these be due to traumatic causes or constitutional tendencies. Elastic pressure gives support to the walls of the vessels, exudation of lymph corpuscles ceases, so much as has already exuded is taken up, and circulation is carried on through natural channels. Of course, if stasis has occurred, a slough formed, or a pus cavity produced, pressure will become an agent of evil instead of an agent of good, unless the pus be evacuated.

Elastic pressure has an application in an important class of cases not yet generally adopted by the profession, namely, in inflammations of the mammary gland. The text-books teach in threatened abscess of the mammary gland that strapping with narrow strips of adhesive plaster is the proper thing to do. If this strapping has ever been accomplished to the satisfaction of the operator, it has been outside the experience and observation of the present writer. Orthodox treatment has been painful, protracted, and inefficient, and this whole business is a standing reproach to the profession. The treatment of these cases of threatened mammary abscess by means of elastic pressure may be conducted quickly, safely, pleasantly. Take a piece of rubber dam, known among dentists as coffer-dam, about eight inches square, perforate the centre with a hole large enough to admit the nipple of the affected breast. Tie four tapes, one to each of the four corners of the rubber dam. Pass the nipple through the perforation, and carry the tapes around the body and over the shoulders in such manner as will press the gland equably and firmly against the ribs. This pressure, in the first place, supports the breast as in a sling, and removes the pain due to sense of weight and dragging. In the second place, superfluous blood is driven back into the circulation, thereby relieving the congestion. In the third place, the lacteal secretion is forced along its natural channels, to be discharged at the

natural outlet, either spontaneously or by a little coaxing with the breast-pump. This appliance in no way interferes with the use of belladonna ointment or other embrocations, and, of course, constitutional treatment would meet the indications as they arise. This same appliance to a secreting, but not inflamed gland, would cause the lacteal secretion to disappear in a few days. If the inflammation has gone on to suppuration, after evacuating the pus, the application of elastic pressure would greatly relieve suffering and hasten convalescence.

In considering the extreme frequency of inflammations of the mammary gland, the protracted suffering to which every victim of mammary abscess is subjected, the inefficiency of all treatment heretofore recommended, any plan that would control the suffering, and restore this important gland to its functions, must be hailed with delight by every lover of his race. Certain it is, if proper care and watchfulness be exercised with the means mentioned above, no case of incipient inflammation of the mammary gland need go on to suppuration; and if suppuration have already taken place, weeks of suffering may be saved by the judicious use of elastic pressure.

It is not supposed that a tithe of the uses of elastic pressure have even been hinted at, but a few thoughts on this subject reaching so many readers through the columns of a widely-read journal may develop facts from other sources, and may redound to the good of the profession.

A BROKEN SQUIER'S VERTEBRATED CATHETER REMOVED FROM THE BLADDER WITH A BIGELOW'S EVACUATOR.

BY WILLIAM A. BYRD, M. D.,
of Quincy, Illinois.

Before the introduction of Nelaton's soft rubber catheter to the notice of the profession, catheterization of a patient with hypertrophy of the prostate gland was an operation requiring considerable skill and tact in the operation, many times the operation failing for the lack of instruments with special curves. To obviate this difficulty Dr. Squier invented a catheter made up of short silver tubes, fitting over each other and moving one upon the other, somewhat like the vertebrae of the spinal column. These were connected to a long tube for the distal extremity. Through all passed a rod with a chain upon the proximal end. The catheter was made more or less flexible by tightening or loosening a nut at the extremity of this rod. This catheter was an admirable arrange-

ment for patients that required their urine drawn twice a day for any considerable time, as it permitted them to use it without the skilled aid of a surgeon, something that few were able to pay for for a great while. It could not but strike most surgeons that there was great danger from the use of such an instrument if it was not kept in perfect order, otherwise rust would destroy the chain, or the rod it was attached to, permitting the vertebrae to drop into the bladder.

November 20th, I was telegraphed for by Dr. Daniel Ellis, of Augusta, Illinois, to come up to remove a catheter in a man's bladder. When I arrived, I found that the patient lived several miles in the country. We started; that is, Drs. Daniel Ellis, R. J. Grigson, James Ellis, a medical student, and myself. We arrived at the patient's house about midnight, and found a very intelligent gentleman of 71 years, anxiously awaiting us. We put him under an anæsthetic, that is, a mixture of, by measure, chloroform three parts, bromide of ethyl one part, and alcohol four parts, of which about one and a half drachms was given through a Hutchinson's inhaler. Though prepared to perform perineal section, I thought I would see if the catheter could be removed with a Bigelow's evacuator, having one of Dr. Bigelow's latest instruments with me. I inserted a curved catheter of No. 19, American gauge, and attached the aspirator; at the third aspiration, in less than one minute, the silver vertebrae, chain, and part of the connecting rod, were deposited in the catch-basin. We left the old gentleman feeling quite comfortable an hour later, and came into Augusta in time for the early train home. The old gentleman had had an attack of retention of urine with over-distention of the bladder some two years before. Dr. Ellis was sent for, and removed three quarts of urine with the catheter. From that time the urine had to be drawn night and morning. He used Nelaton's catheters for relief, but they became useless in a short time, on account of not having the oil washed off after each time of their use, and he found that a Squier's catheter, that he obtained of Dr. Grigson, passed much more easily than a rubber instrument. Dr. Grigson found one of the links of the chain in his instrument so eroded when it was returned to him, that it broke while handling it. Another instrument of the same kind was obtained, and this it was that broke when he started to withdraw it after using it. The rod had become eroded about half-way down, and broke into two pieces.

The catheter might have remained sound and

useful much longer had it been carefully washed and oiled after each introduction, but the friction of the links of the chain causes a rapid wear, and renders the instrument extremely liable to break, and of course is very dangerous to the patient. Nothing could have excelled the evacuator for the removal of the pieces of metal, and the patient was saved from undergoing a dangerous operation. with a lingering recovery.

416 Jersey street.

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE
BELLEVUE HOSPITAL MEDICAL COLLEGE.

BY LEWIS A. SAYRE, M. D.,

Professor of Orthopedic Surgery to the College.

Reported by EDWARD DEVELIN, M. D.

Spondylitis. *Clinic by*

Sayre
GENTLEMEN: This little child that I now present to you is suffering from spondylitis in the earliest stage.

The parents and other members of the family are perfectly healthy; and this child, beyond the difficulty of the spine, presents a remarkably robust appearance. I am informed that she commenced to complain of pain in her back and side, and of considerable difficulty in breathing, some six months ago, becoming restless, nervous, and irritable. Previous to this she had injured herself in falling from a chair. You will notice that there is a projection of the spine at the eleventh dorsal vertebra, and that as she stoops down to pick anything up from the floor, she avoids bending the spine, but flexes the legs upon the thighs, and the thighs upon the abdomen, thus squatting down and maintaining the spine in the erect position.

Now, as I lay the child upon her abdomen across my knees, the thighs and arms hanging down on either side, as you see, I slowly separate my knees, and in this manner make gradual traction, by this means extending the spinal column, and relieving the diseased surfaces of the vertebrae from pressure, and thus free the child from pain, as you observe the instantaneous change in her manner of breathing; from the short, quick, jerky respiration, to a deep, full, long inspiration, and the child seems perfectly comfortable. Now by drawing my legs closer together, you notice the immediate return of the previous spasmodic breathing; and now placing one of my hands upon her head, and the other upon her buttocks, and pressing the vertebral column together, she immediately begins to cry with the pain produced, and there is at the same time an instantaneous spasm produced in her legs. Now by gently separating my knees again, and extending the spine, her sobbing ceases, and she states that she is quite comfortable again. You now observe that I am making firm pressure over the spinous processes at the seat of the disease,

and, according to all authorities, this should increase the pain; whereas, as you can plainly see, it does not do so. But, on the contrary, when slight extension is made upon the column, and direct pressure with your finger over the projecting spinous processes, there is rather a tendency to relieve the pain, by opening the angle of pressure in front of the vertebrae.

I have found that in these cases of antero-posterior curvature of the spine, by placing the child in this position, and gently pressing downward, at the same time making your traction as I have just described, you relieve the patient. The explanation, to my mind, is simple enough, viz: by these two manipulations (the disease being situated in the anterior portion of the vertebrae), you relieve the inflamed surfaces from pressure, and, as it were, separate the anterior edges of the vertebrae from each other. This latter, of course, is an impossibility, but at the same time sufficient force is brought to bear by your combined manipulations to relieve the diseased surfaces from pressure, and hence the cessation of pain.

This examination we have now made will reveal the disease if it be in the anterior part of the bodies of the vertebrae; but there may be some cases in which the examination we have just made will reveal no evidences of disease at all, and at the same time there may be spondylitis existing. But by a more careful examination you will find the disease upon the side of the bodies of the vertebrae, and it has been caused by some blow or pressure upon the ribs, driving the heads of the ribs into their facets. You detect the disease in this position by pressing upon each rib separately, and the moment you come to the point of disease the patient will flinch with the pain induced by your pressure.

Having now made our diagnosis, I call your attention to the treatment of the case. I shall here apply the plaster-of-Paris jacket and *jury mast*: and will now show you the method of its application.

The child has already been thoroughly cleansed, and we put upon her a skin-fitting knitted woollen shirt tied over the shoulders, manufactured expressly for this purpose by the Bickford Knitting Co., 841 Broadway, this city. We now fold two towels and pass under the shirt in front, allowing them to extend the full length of the trunk. This is to prevent pressure upon the viscera, and allow of free respiration and expansion of the abdominal walls after eating; these towels being withdrawn as soon as the plaster has become sufficiently set. Having now adjusted the towels, the shirt is drawn down tightly and secured between the legs with a safety pin, and your patient is then ready for the partial suspension necessary during the application of the plaster-of-Paris jacket.

The child we now place in the suspending apparatus (see Fig. 1), which you will notice consists of an iron cross-bar with a chin collar of soft leather, and arm supports also. Having carefully adjusted this so that the weight of the body is borne evenly upon the arm-pieces under the axillae and the chin collar which supports the head, we make gradual traction upon the vertebral column until our patient states that she is perfectly easy and free from all pain. In this case you will no-

tice that the traction necessary to secure this result, is sufficient to slightly raise the heels from the floor; in some cases this is not necessary, and again in others the traction required may be still

FIG. 1.

greater; but never under any circumstances should your traction be so great as to lift your patient *completely from the ground*. This I desire you to specially understand, otherwise the word *suspension*, used in our description of the treatment, may lead you to suppose that the patient is to be literally suspended, when in reality it is but *partial suspension*.

This child then is fully prepared for the application of the jacket, and I will at once show you the manner in which it should be properly applied. You will here notice that I have from eight to twelve rolls of bandages formed of crinoline, into the meshes of which the dry plaster of Paris has been well rubbed and then rolled up moderately loose; not by any means as tightly as the ordinary roller bandage used in surgical dressings, but sufficiently tight to retain the plaster in the fabric, and at the same time allow of it becoming saturated to its centre rapidly when placed on the water. These bandages vary from two and a half to four inches in width, and also being from three to four yards long, depending upon the size of the patient.

I now place a roll of the bandage in a pail of tepid water, which is sufficiently deep to cover the bandage when standing upon its end, and then wait until it has become thoroughly saturated, which is shown by the cessation of the escape of air from the water. I again place another roll in the water, that it may become saturated while I am applying the one previously immersed. This one, as you observe, I now remove, and pressing

out all surplus water, I carefully wind it around the waist of the child, my two assistants rubbing each layer of the bandage well into the preceding one. I would here call your attention to the manner in which I commence the application of the jacket, viz., at the waist, gradually going down until I come to just above the great trochanter. Then carefully reversing the bandages, as you see, I pass upwards again, and having secured sufficient thickness at the waist, I then pass on up the trunk, until I am on a line with the axillæ, and a little higher in front over the chest, and also higher over the scapulæ at the back. In some cases you will find it necessary to put padding between the shirt and your plaster bandages, over the sacrum and crests of the ilii, and also on *either side of the projection of the vertebra* where the disease is located, in order to prevent excoriation of these parts. But never put any padding upon the projection of the vertebra, but place it upon either side, to prevent pressure upon that point. If you fail to do this and allow of pressure to be made there, it may result in a painful ulcer, which will delay your treatment many months: for if such an ulcer should be started the jacket must be at once removed and the patient placed in bed, until such time as it shall have healed, when the jacket may be again applied. I do not wish you to under-estimate the importance of this careful padding. It is not the plaster-of-Paris that is going to effect a cure of this disease, but your skill in its application, and formation of a jacket by its use which will support and relieve the diseased surfaces from pressure, until such time as all morbid changes have been checked, and a healthy action set up in the hitherto diseased parts.

Now, in this case, although the disease is low down, I shall apply the *jury mast*. (Fig. 2.) In some

FIG. 2.

cases where the disease is so low down, I have

omitted the jury mast, as its appearance is oftentimes objectionable. My friend, however, Prof. Samuel W. Gross, suggested that it be used in those cases in which the disease was low down as well as high up in the spinal column, and stated that he had secured much better results in its general application. I most heartily endorse his suggestion, and now apply it in almost every case of spondylitis.

You have observed that I have now shaped the lower portion of the *jury mast* to the back of the child, the lower part of the instrument consisting of these two iron strips which pass upon either side of the spine to the exact contour of the child, and it is now placed in the centre of the body, the bars running up on either side of the spine, the strips of perforated tin which you here see passing from the iron bands two-thirds around the body of the child. My assistant now retaining this firmly in position, the central rod running over the back of the head to the vertex, we again continue the application of the plaster bandages until the lower portion of the instrument is securely embodied in the jacket, my assistants, as you observe, rubbing each layer of the bandage into the preceding one.

You have now seen how simple the method and easy the application of the plaster-of-Paris jacket is. This child should now be laid upon an air bed, but as this is not at hand, we must substitute the ordinary hospital bed, and allow her to remain there until the plaster has become thoroughly set; it is then to be trimmed out under the arms and in front of the thighs, to allow of perfect flexion of the limbs; after which time the leathern collar which I here show you, is placed under the chin and occiput, then by the means of these two straps on either side, which pass up, one over the inferior maxilla, and the other from the occiput to this small cross-bar attached to the central rod of the jury mast (see Fig. 2), our support is secured for the head and by means of which the entire weight of the head is removed from the spinal column if the straps of the head-rest be properly adjusted. You must, however, at all times be certain to get your central point of traction or suspension by means of this cross-bar at the end of the jury mast, immediately above the vertex of the head; leaving room at all times for a cap or hat to be worn upon the head under the instrument. At no time must the jury mast press upon the head; the distance desirable between the cross-bar and the top of the head is from three to four inches.

In removing the child from the suspension after the jacket has been applied, you must be extremely cautious that you do not allow her to bend her back before the plaster has set, otherwise your labor will have been lost. Also while applying the jacket, see that you carefully mould the jacket in above the crest of the ilia, so as to secure a shoulder for your jacket, but do not mould it in so severely as to cause pressure or excoriations.

Case 2. This little fellow, four years of age, whom I here present to you, illustrates an extremely interesting feature in the application of the plastic jacket in its worst possible manner. You are probably wondering, as the child now stands leaning over the chair for support, what man, calling himself a physician, could be bar-

barous enough to put such a thing upon this poor child; and independently of that, to expect satisfactory results from such treatment. Such an application can result in nothing but disaster to the child, as shown in the suffering depicted upon his face: and yet this man who applied this so-called plaster jacket, I am told by the father of the child now before you, stated that he had studied under me in my office.

I will now remove this casing, such as it is, and ask you if any one of you, after seeing me apply the jacket as in our previous case, could possibly imagine that such a man had ever seen a plaster jacket in his life. You notice that I cut easily through a few soft, wrinkled bandages, having a little plaster in them, but affording no more support than the ordinary roller bandage. Cutting through this, we now come down to a layer of cotton next to the skin, and around which the plaster bandages have been passed. There is no knitted shirt, or shirt of any kind; nothing but this layer of cotton and these few bandages, which you see I can roll or twist up in any form.

Is it then any wonder that at times the *Sayre plaster of Paris jacket* should fall into disrepute: when a man, calling himself a physician and living in the city of New York, should dare to put on such a misrepresentation, and claim to have been three years in my office, and putting on plaster of Paris jackets under my guidance? I have looked the directory through for this man, but I cannot find his name. It is now some months, the father states, since this was placed upon the child.

You will notice that the boy cannot stand but for a moment, and even then must support himself by placing his hands upon his knees. He at present is in no condition to be suspended for the application of the jacket, being in a greatly exhausted condition. I shall therefore direct that he be kept in bed until our next clinic, with perfect rest and good nourishing diet; when he will in all probability be in such a condition that the jacket and jury mast can be properly applied.

You will notice that as I lay the child across my knees, as in the previous case, and extend the spinal column, instantly there is an expression of relief, and he breathes more easily, and also tells us that "it feels better."

NOTE.—Jacket and jury mast applied one week later; after the jacket had become set, the child walked around with comfort and ease, and said he was "all right now."

MEDICAL SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Enormous Hypertrophy of the Heart (Weighing Forty-eight Ounces.)

PRESENTED BY CHARLES W. DULLES, M. D.

Thursday evening, December 13, 1883, Dr. J. H. Musser in the chair.

The patient from whom this specimen was obtained was a young man, eighteen years of age, who came under my care in February, 1882, in an attack of muscular rheumatism, principally affect-

ing the shoulders. I found at that time great oppression of breathing, a heart dilated and hypertrophied, with a harsh, strong, mitral systolic, and presystolic murmur. His urine contained bile, coloring matter, great excess of urates, great lack of chlorides and phosphates, and no albumen, or sugar. In the sediments only amorphous urates were found. The treatment employed included the administration of infusion of digitalis, with iron and strychnia. At one time, believing it might benefit the violence I attributed to the real hypertrophy, I gave him *veratrum viride*. But it did no good. I did, however, get apparently good and prompt relief from some of the symptoms by the use of iodide of potash, in twenty-grain doses, thrice daily. After using this for a week, I noted in my case-book: "Sleeps well; eats well; feels well; cough very slight; urine clear; pulse better; *cannot hear the old murmur!* (perhaps barely); both heart-sounds audible and pretty clear; action of heart fair." (It had been very tumultuous.) After six weeks of doing well, the patient had a new attack of uneasy stomach, dyspnoea, and more or less cyanosis. On the night of May 10 he had a frightful attack of dyspnoea. I gave him gr. $\frac{1}{2}$ of muriate of pilocarpine hypodermically (in the left arm), under the influence of which he sweated, but had no salivation.

The next day he had a large oedematous swelling of the left side of his neck, below the jaw, and reaching to the middle line in front. This increased up to the evening, and gradually subsided in three days.

About this time fluid began to accumulate in the abdomen and thorax, and there was, of course, oedema of the feet and legs. There was also heard now a most beautiful water-hammer pulse over the femoral arteries below Poupart's ligament. The pulse here was intermittent and had a reduplicated sound like this, . —, . —, . —, . —, etc.

Three weeks later another severe attack occurred, and again about three weeks after this. There were now in his urine considerable albumen and hyaline tube casts. When his attack came on, which was at night, I gave him gr. $\frac{1}{4}$ of the muriate of pilocarpine hypodermically, which produced free sweating, and brought out about f $\frac{3}{4}$ ij of saliva. His pulse came down from 140 to 100 in half an hour. But the dyspnoea abated only temporarily; the restlessness continued; the cyanosis increased; the respirations varied from 35 to 60 per minute; then his bowels moved involuntarily, his lungs seemed to fill up with oedema, and he died asphyxiated.

The autopsy was made the next day, with the assistance of Dr. Formad and Dr. J. H. Musser. The points of interest were as follows: General oedema of feet and legs; the face and neck and chest covered with purpura-like spots and patches. The abdomen contained about two quarts of clear serum; each pleural cavity nearly as much. The lungs were normal, but small, and occupied the upper part of the chest. They were quite oedematous. The liver was slightly fatty, the spleen was of normal size, but very hard and tough. The kidneys were large, congenitally lobulated, and in a state of cyanotic hypertrophy.

The heart was enormously hypertrophied, weighing, when all the adherent parts were re-

moved, 48 ounces. The pericardium was so uniformly attached to it that it could not be removed, and there was absolutely no pericardial cavity. The right ventricle contained about six ounces of soft post-mortem clot. The left side contained about two ounces similar. After the heart had been opened and cold-washed, it weighed 40 ounces. All the valves and blood vessels were healthy. The tricuspid and aortic valves were quite competent. The mitral orifice was enormous, measuring $2\frac{1}{2}$ inches across. Every part of the heart was hypertrophied, and all to about the same degree. The whole organ, which I here show, was about the size of that of a bullock.

The points of interest in this case, aside from the curiousness of the specimen, seem to me to be: the comparative immunity of the kidneys; the absence of signs of adherent pericardium; the benefit derived from the use of iodide of potash; the temporary disappearance of the very strong mitral systolic and presystolic murmur; and the parotid swelling following the hypodermic injection of pilocarpine in the arm of the same side.

Dr. J. H. Musser remembered distinctly the case both before and after death. He had marked out on the chest the dimensions of the heart, and made it out as enormous, extending especially to the right. Furthermore, he thought that there was a double mitral murmur. The only apparent cause for the hypertrophy was the adherent pericardium. He would like to know what Dr. Henry thought of the correctness of this explanation.

Dr. F. P. Henry said that the heart presented was remarkable not only for its enormous size, but also for the absence of the usual causes of cardiac hypertrophy, there being neither valvular disease nor obstruction in any part of the circulation. During his student days he had seen some very large hearts in the collection which Prof. Alonzo Clark was accustomed to show to his class, but would not trust his memory so far as to affirm that any one of them was as large as the one just shown.

Dr. MacConnell had seen a case in a member of the Modjeska troupe, where post mortem examination showed an enormously hypertrophied heart with adherent pericardium, and markedly granular kidneys. In this case the hypertrophy was clearly due to the kidney trouble.

Dr. Formad thought that Dr. Dulles's case was unique as to size. Dr. Robinson, of New York, had recently reported a case of hypertrophied heart weighing 56 ounces, but Dr. Dulles's specimen was weighed after removal of clots, etc. Dr. Musser asked whether other members of his patient's family had not hypertrophied hearts without valvular lesions. If such was the case, taking into consideration the age of the patient, it would be well to consider the probability of the hypertrophy being in part secondary to the pericardial adhesions, in part idiopathic in origin. Dr. Dulles said that there was a tendency to hypertrophy of the heart in one sister, and that the murmur at times was double.

Calcified Pericardium—Double Mitral Disease.

Ella S., white, at. twenty-three, was admitted to the University Hospital, September, 1880, complaining of palpitation and dyspnoea, and suffer-

ing from an oedematous and eczematous condition of the lower extremities. She was a girl of regular habits, somewhat exposed to changes of weather and to wet, doing no very hard work. She had had the diseases peculiar to childhood, but never rheumatism nor chorea. Her father had had acute articular rheumatism, and died suddenly; beyond this, there was nothing peculiar in the family history. Three years before admission she first noticed slight palpitation and dyspnoea on exertion. For some time before that she had been subject to frequent attacks of epistaxis. One year afterward dropsy appeared in the ankles and spread upward. The palpitation and dyspnoea became more troublesome, her flesh and strength failed, and she was compelled to quit work and come into the hospital. When first seen she was pale, anæmic, weak, breathless on exertion. The heart's apex beat was in the seventh interspace, one inch outside of the nipple line; action strong and heaving. Best heard over the apex beat, but transmitted feebly up toward the base of the heart, and well out into the axilla, was a loud blowing systolic murmur. There was no pain in the heart, nor tenderness on pressure over it, nor had there ever been. Over the lungs were scattered moist râles; the respiratory murmur was harsher on the left than on the right. Cough was slight, with some mucous expectoration. The lower extremities were oedematous, and the abdominal cavity about half filled with fluid. The liver was slightly enlarged. The urine was normal in quantity, and contained neither albumen nor casts. Under treatment the urine became copious, the oedema gradually disappeared, and the heart action became stronger and more regular. In a few days friction-sounds appeared at the base of the right lung. Any slight exposure would bring on an attack of intense congestion of the lungs, with dyspnoea, that often threatened life; and with these attacks there was often congestion of the kidneys with suppression of the urine. Between the attacks, the heart retained its power well, though it slowly dilated. At intervals she complained of dull pain in the hepatic region. The rough respiration noted at first over the left lung became more and more marked, till finally, over a small area just below the spine of the scapula, it had developed into bronchial breathing. Friction-sounds came and went. There were always moist râles scattered through the lungs. The expectoration was mucous, or rarely muco-purulent. Three months after she came under observation there was developed at the second right intercostal space, and carried out into the arteries of the neck, a systolic murmur differing in pitch and tone from the mitral systolic. About this time, too, she complained of pain in the heart whenever its action was excited. Soon afterward albumen was found in the urine, but no casts. This was the only time it was ever detected. Fourteen months after she was first seen there was noticed, just inside the apex beat, and carried indistinctly toward the base, a harsh, short murmur, immediately preceding the systolic murmur and separated from it by an exceedingly short, but appreciable interval. This murmur was noted on several occasions afterward, but was much more frequently absent than present. Its appearance and disappearance seemed to be at-

tendant on no definite conditions. Soon after it was first noticed she had several attacks of epistaxis, and afterward occasional slight hemorrhages from the lungs. She was discharged in March, 1882, and was readmitted last September. She had been gradually losing ground. Seven months before she took cold, the dropsy returned and persisted. When seen, the whole body was oedematous, and the abdomen enormously distended. The apex-beat was in the fifth interspace, in the mid-axillary line. The systolic murmurs were, perhaps, louder, but beyond this had not changed. Over an area between the left nipple and the sternum was heard a harsh, low-pitched presystolic murmur. It was much more apparent than the former presystolic murmur, but had the same characters. Its point of maximum intensity was just to the left of the sternum. It was constant. The respiratory murmur over the left lung was very much harsher than over the right. Below the spine of the scapula the breathing was sometimes blowing with mucous râles, sometimes cavernous with gurgling râles. The expectoration was mainly frothy mucus. She died three weeks after admission, in a fit of dyspnoea.

Autopsy seven hours after death. General dropsy, most marked in the lower extremities and genitals. On the lower part of the abdomen there is a marked varicose condition of the cutaneous lymphatics. Cavity of the pericardium is completely obliterated by adhesions. The two pericardial surfaces, and the fibrous tissue connecting them, had been changed into a calcareous plate three inches broad, completely encircling about its middle the heart, with the exception of a space one inch wide on the posterior surface of the left ventricle. This calcified condition extended for one inch on the anterior surface of the pulmonary artery. The heart, with the calcified pericardium, weighed twenty-eight ounces. The auricles were dilated, their walls thinned. The ventricles were dilated, their walls thickened and undergoing fatty degeneration. The leaflets of the mitral valve were thickened and rigid; the mitral orifice was very decidedly narrowed. In the inner surface of the left auricle were several calcareous patches. The aorta was very small, scarcely admitting the index finger, and showed patches of atheroma. The lungs were chronically congested and oedematous, the condition being most marked on the left; there was no breaking down of their substance. The abdomen contained five gallons of straw-colored serum. The peritoneum was thickened and roughened. The liver weighed three and one-half pounds, and was cirrhotic. Its capsule was much thickened and adherent to surrounding structure. The mucous membrane of the stomach was thickened. The kidneys showed cyanotic induration.

Section of Fibroma Mammæ.

Presented by Dr. MacConnell for Prof. Pancoast.

The patient was 22 years of age, and the growth was of seven months' duration. Fibromata of the breast are very frequently found, although some English authorities consider them to be of rare occurrence. They have been variously described, under different names, by writers. Birkett considers them a form of adenoma; Broca, adenoma with predominance of stroma, etc., etc. This

tumor was of an ovoid shape, firm and elastic, and on section presented a maroon-colored tissue, which under the microscope is seen to be composed of dense bundles of mature fibrous tissue, with but few nuclei. In some portions, bands of wavy connective tissue are seen. The epithelial elements of the acini are hyperplastic.

Section of Large Spindle-celled Sarcoma of Lower Jaw.

Exhibited by Dr. MacConnell for Prof. Pancoast. The patient was a man, æt. 24 years. The growth had existed for about three years. The egg-shell crackle was readily elicited, the growth being of a central origin. On section it presented a whitish appearance, and was permeated by spicula of bone.

Liver of Chicken with Tubercular Growths.

Exhibited by Dr. MacConnell.

The microscope clearly proved the nature of the growths.

Dr. Formad had seen four or five similar cases in the chicken, and two in the turkey, in all of which he had detected tubercle bacilli.

Dr. Barton was much interested in two of the specimens presented by Dr. MacConnell. He was much surprised as to the nature of the tumor of the jaw, in that it was a spindle-celled and not a giant-celled sarcoma. Its site and duration would clinically have clearly indicated one of the myeloid variety. The sections of the mammary growth differed from those examined by him, in that in adeno-fibroma the glandular elements were more evenly distributed, whereas this section reminded him of his former studies of an elderly normal gland; such large tracts are found without any traces of gland tissue, whereas, in all adeno-fibromas examined by him the adenomatous and fibrous elements were relatively more evenly distributed, giving the idea of the neogenesis of both, and not the atrophy of one and the proliferation of the other.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated meeting, Thursday, January 3, 1884, the President, R. A. Cleemann, M. D., in the chair.

Batley's Operation.

Dr. E. E. Montgomery corrected a statement made in the report of the case of ovariectomy narrated by him at the meeting of December 6, 1883, (see REPORTER, January 5, 1884, p. 14). *Silk ligatures*, not catgut, were used to tie the pedicles.

The convalescence of the patient had been very satisfactory. The temperature did not rise above 99° F. In performing this operation no antiseptic was used, all instruments, sponges, etc., were washed in boiling water, and boiled water was used in washing the wound and abdominal cavity. The mental condition of the patient was such that she was kept constantly under mechanical restraint, and on one occasion, when she had been left alone for a few minutes, she tore all the dressings off of the wound, and at the next visit it was found bare, but no bad result followed. The sutures were removed on the eighth day. Some pain in the lower part of the abdomen and slight fever commenced on the twenty-fifth day, but she

has since again improved. Her mental condition is at the present better than it had been for a year before the operation, and she can now converse rationally.

Septicæmia after Abortion.

Dr. W. H. Parish reported the following case: A young woman, twenty years of age, came into the Philadelphia hospital in the finishing stages of an abortion which had been coming on for some days. The cause was unknown, but was probably instrumental. At the time I first saw her, three days after admission, her temperature was 103° to 104° F., and pulse 150. She had had a chill before admission, her abdomen was distended and tender, and the uterus was very sensitive. The right parotid gland was swelled and painful. It continued to enlarge, and fearing septicæmia, he gave fifty grains of quinine daily by rectum, as the stomach was too irritable to retain it; one ounce of whisky was given by the mouth every hour, day and night. A small quantity of morphia was given to relieve the abdominal tenderness. The pulse and temperature fell rapidly, but the gland continued to be swelled and painful; it was quite hard, but was discolored. There were no chills now, but fearing the presence of pus, he made an opening by Hilton's method, incising the skin and using a director to tear an opening through the gland tissue; this opening was enlarged by passing a pair of forceps, closed, along the groove of the director, and withdrawing them opened. This opening gave exit to two or three fluid-drachms of pus. The gland now improved in appearance, but another abscess opened behind the gland and discharged freely. The two abscesses did not communicate. The patient is now convalescent.

OFFICERS OF THE SOCIETY FOR 1884.

President—Richard A. Cleemann, M. D.

Vice-Presidents—B. F. Baer, M. D.; W. F. Taylor, M. D.

Secretary—W. H. H. Githens, M. D.

Treasurer—Alfred Whelen, M. D.

Librarian and Curator—T. Hewson Bradford, M. D.

Councillors—R. P. Harris, M. D.; Lewis D. Harlow, M. D.; Wm. Goodell, M. D.; T. M. Drysdale, M. D.

Publication Committee—John H. Packard, M. D.; James V. Ingham, M. D.; Elliott Richardson, M. D.; B. F. Baer, M. D.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Discussion on Nervous Prostration. (See page 97.)

Dr. Mills, in opening the discussion, by request of the Chair, said: "I understand that Dr. Bartholow denies that a disease exists, primarily nervous in origin, which can be called neurasthenia. He classes all cases so-called under two heads, congestive and anæmic, and holds that the symptoms presented are chiefly reflex effects of digestive or other visceral troubles. I have no doubt that many cases are to be thus explained, but we have others in which the cerebral condition is primary. In cases with the symptoms as detailed in the paper, we may perhaps clearly ascribe

them to the causes and conditions referred to by Dr. Bartholow, but other cases may be explained in a different manner.

"In individuals whose higher ganglionic centres are so constituted, from bad inheritance or poor training, or both, that they cannot bear much strain, when subjected to this strain, these centres exhaust. We have certain functions called organic functions, respiration, vaso-motor action, etc., with centres in medulla oblongata and spinal cord. These functions must be maintained as long as the individual exists. Their centres must be nourished and sustained in a uniform way. Presiding over automatic movements, they must be kept in the highest tone, must have good blood and plenty of it. It is a principle brought out in the paper that local diversion of blood to any one organ or part will take it from other organs or parts; and we may, in accordance with this, have the higher brain diverting blood from the lower, or lower brain from the higher. We have *nervous* symptoms, the result of this overstrain of nerve-centres, and the disturbance of the equilibrium of the circulation thereby brought about.

"I am inclined to differ from Dr. Bartholow, and agree with Dr. Beard, as to the propriety of the term 'American Disease.' The social and business exigencies in this country are different, are more taxing than in Europe. In England, for instance, men become mature and enter public life at later periods than here. In France the difference is not so great, but the more absolute division of society into grades and castes prevents too fierce a struggle for high position. Here every man has the chance to rise to the highest position, and men enter especially political life in youth. Americans are not trained for special lines of life-work. They often attempt work too high for their mental powers, and break down."

Dr. Tyson: "I have many times asked myself the question, 'What is nervous prostration?' The answer was always, 'It is not a nervous disease, certainly not an organic nervous disease, and probably not a functional one. It is rather a condition of muscular fatigue, and it may be nervous fatigue. Most of the cases are accompanied by digestive derangements, which are responsible for many of the symptoms, most of which are reflex.' At the same time, I admit that some of the symptoms are puzzling, and not easily explained. Among these is the pain in the back of the head, often referred to as the result of 'nerve tire,' and sometimes regarded as an important indication of cerebral disorder, which it is not. In women, uterine derangement is often responsible for the complex symptoms known as nervous prostration.

"The point, however, that attracted me in the paper read, was allusion to the condition of the urine in one of the cases. It was described as dark brown, of high specific gravity, containing a trace of sugar. I have seen such cases, and think it not unlikely that the apparent sugar reaction is really due to uric acid, which is often abundantly present in these urines of deranged digestion. If we get rid of the excess of uric acid, by allowing it to precipitate spontaneously, or precipitate it by the addition of an acid, the sugar reaction with the copper tests does not take place. Other characters of the urine, particularly its

dark color and scantiness, are not usual to sugar-containing urine."

Dr. Eskridge: "The most important point in the subject is whether the condition called neurasthenia is primarily a nervous disorder, or a disturbance in other parts of the body. I would have been better pleased, if Dr. Mills had elaborated more thoroughly his statements as to the organic functions. He said these functions must be well nourished, and that failure in them is due to failure in the upper nervous system. I would have liked if he had gone further in his explanation. Is this failure due to disturbance in the brain and upper portion of spinal cord primarily, or to failure in other parts of the body? Those who have paid attention to this subject say that breakdown does not occur unconnected with either worry or vice. I have never seen a case from mental over-work alone. In five cases of neurasthenia, of which I have notes, one was from sexual excess; two from worry connected with family troubles; another from alcoholic excess, with sexual vices; and the fifth from sunstroke, followed by over-sexual indulgences. In the last case it seemed as if the brain was primarily at fault. It appears to me that nervous prostration, so-called, is a depressed condition of the whole system; the trouble manifesting itself as a general nervous condition secondarily, after organs other than the brain have been primarily affected. The therapeutics also favor this view, because the cases are benefited, not by agents addressed to the nervous system alone, but by hygienic and tonic measures."

Dr. Glasgow: "I have come to regard these cases as not nervous in origin, but as largely due to digestive troubles. They are cured by attention to the disordered functions. I have known a short residence in Atlantic City, without any medical treatment, to suffice for a cure."

Dr. Bartholow, in closing the discussion, said: "The great question is, Is neurasthenia functional, or does it arise from organic change in the nervous system? I maintain that it is largely reflex, and frequently from gastric disturbance. Neurasthenia in women is associated with an anæmic condition and ovarian and uterine disorders. They are pale and weak, and if they are subjected to any moral or mental trouble, give way, but if they are well nourished sustain any kind of shocks without suffering in health.

"In regard to the term 'American Disease,' and to the claim that the peculiar conditions of American life are causative of neurasthenia, it will suffice to say that in some of the European states a higher grade of education is maintained than in this country. In Prussia, for instance, every one is taught to read; education is more general than in Massachusetts. The struggle to maintain existence, and hence the demands on the brain, are severer than here; and although neurasthenia is said to be uncommon, there are diseases similar to that called nervous exhaustion in this country, arising from similar causes.

"Worry has been mentioned as a cause of nervous exhaustion: now, worry hurts a man just in proportion to his condition. If he is in good health, or phlegmatic in temperament, the worry may be well borne; but if he is out of health, worry will have a powerful effect on the nervous

system. I do not deny that various causes may produce brain disease, but I deny that the so-called neurasthenia is due to an organic lesion of the nervous system. I maintain that it is a part of

a morbid complexus; a reflex condition, in large part, of maladies situated in the stomach, the liver, the uterus, or other organs."

EDITORIAL DEPARTMENT.

PERISCOPE.

Colds.

We take the following from the *Lancet*, November 14, 1883:

Colds are chills, and chills are prolonged depressions of nerve-force, without the reaction which should occur immediately after the collapse. Nineteen persons out of twenty misuse this word "reaction," and the misuse involves more than an error, or confusion, of terms. There are three stages of every strong impression made on a living organism. First, the attack—in this case the chill; second, the pause, like a dead-point, during which the organism is depressed—that is, lying under the stunning effect of the attack; and third, the reaction. The "reaction" cannot occur until after the dead-point, and the mistake commonly made is to speak of the stage of exhaustion or depression which follows any severe impression as the reaction, whereas it is precisely because no reaction occurs and the dead-point is prolonged that matters go amiss. The physiological, or perhaps we ought to say the pathological, process of a cold has been thus described: When the surface of the body or the air-passages are chilled by a draught, or by being drenched with rain and sitting in cold, damp clothes, lying in damp sheets, and the like, the mischievous impression is made, not on the skin itself or on the lining membrane of the air-passages, but upon the vast network of minute nerve-filaments which lies beneath these membranes, and connects the surfaces of the body—both external and internal—with the nerve-centres, which are the sources and foci of energy and power. These nerve-centres receive, through the multitudinous branches of telegraph-like afferent nerves converging to them, a shock or staggering impression which for the moment paralyzes them; and during this paralysis or stupefaction the vaso-motor, or vessel-contracting centre, whose peculiar function it is to regulate the calibre of the blood-vessels, gets the upper hand, and these blood-vessels are contracted so that they carry less blood than usual. The smaller branches of the arterial system, which form a net-work immediately underneath the skin and give it its bright pink color, are so reduced in "bore" or calibre—as any elastic or compressible tube may be reduced—that the red blood does not flow through them, and the surface looks pallid. This is the first effect of "chill." Presently comes the recovery from this state, or the "reaction" as it is called, when the first effects of the shock have passed away and the centres begin to revive. Now occurs the critical moment. If the shock

has been great, and the recovery is slow or imperfect, as often happens in a depressed or what is called a "delicate" state of the organism, the vaso-motor centre, which, of course, shares the general depression, though it is not the first to feel it and show it, will give way before the reaction is established; and then the heart, bounding in its recovery, pumps its blood into unduly-yielding and unstrung vessels, and dilates them, and local congestions or accumulations of blood may take place, while the absence of proper resistance excites the heart to tumultuous action, and the disturbances of fever and inflammation occur. It is a question of the balance in power between two parts of the nervous system, the general and the particular—the latter being the centre that regulates the calibre of the blood-vessels—and this practically resolves itself into a question of time. If the reaction of the general nervous system be quick, there is a rush of blood to the surface vessels, and due resistance being found, the heart quickens its pump-like action, and the sweat-glands are thrown into activity, so that perspiration ensues. If, on the other hand, the vaso-motor centre has participated seriously in the shock of the chill, the muscular coats of the vessels are not properly contracted; they have lost their tone. Then the blood propelled to the surface simply dilates the vessels, so that there are the redness and heat of "fever" or pyrexia, and the skin remains dry; there is rapid action of the heart, partly because there is less than the normal resistance to overcome, and partly because the vagus fails to exert its inhibitory action, and both the muscular structure of the heart and the respiratory centre are left uncontrolled, but the current of the blood moves slowly through the vessels, and the heart-wave is perceptible in the arterioles, and is present in the capillary area.

Coincident with these mechanical actions and reactions, involving departure from the healthy condition of the circulation, occur disturbances of the chemical processes of health, and consequently alterations in the nutritive relation of the various tissues of the organism and the blood. What then is a cold? Clearly it is a disturbance of the balance between the several parts of the nervous system, brought about by the shock of a sudden or prolonged exposure to the depressing effect of "chill"; although the same physiological results may be produced in the organism by the operation of any agent which is capable of giving the nervous system a similar shock, and thus creating the same kind of disturbance. Nature's provisions against the consequence of a "chill" and for the prevention of a "cold" are *sneezing and shivering*. A violent fit of sneezing often saves a chilled

body the consequences of the nerve depression, or "shock," to which it has been subjected; and this shock may in its first impression be very limited in its area; for example, the small extent covered by a draught of cold air rushing through the crevice of a door or window. The nerve centres are aroused from their "collapse" by the commotion or explosive influence of the sneeze. If sneezing fails, nature will try a shiver, which acts mechanically in the same way. If this fails, the effects are likely to be very serious, and bad consequences may ensue. The popular notion reverses the order of events, and hence the saying, "If there is sneezing the cold will be slight, if there is shivering it will be grave;" whereas it is slight when sneezing suffices to recover the nervous system quickly from its depression, and grave when even strong shivering fails to do so. In case of chill, with threatened cold, sneezing may be produced by a pinch of snuff of any kind. This is how some of the vaunted "cures" of cold by snuff are brought about. Or brisk exercise may ward off the attack. The popular idea is that the circulation is restored by these remedies, but the true explanation is that the nervous system and centres are aroused. The first step towards an intelligent treatment of chill and cold is a scientific recognition of their nature.

Nervous Derangements of the Heart.

Before the Medical Society of London (*Lancet*, November 24, 1883), Dr. Milner Fothergill read a paper on some "Nervous Derangements of the Heart." He said that the organic diseases of the heart usually force themselves upon the notice of the patient by some indirect symptom—as shortness of breath on exertion—rather than directly. With the neural affections, on the contrary, the attention is drawn to the heart directly and immediately. This constitutes a broad main line of demarcation betwixt disease and disorder of the heart. The first form of disorder was intermittency, a halt in the rhythmic stroke of the heart. As such, it is a mere "neural halt," though it is not uncommonly found in elderly men who may at the same time be the subjects of degenerative changes. In these cases, when the halt is increased by an effort, it has a suggestive value; even then the halt is usually less felt by the patient than is the true neural halt without any disease. Sometimes the halt is found in the radial pulse, when the heart's stroke can be heard; this tells of an arterial blood-wave too feeble to reach the radial artery. Then palpitation not linked with effort, but coming on at other times when quiet is being observed, or even waking the patient up from sleep, is neural in character, though having varied causal relationships. Not rarely it is due to some disturbance in the reproductive organs, especially in women. Pain in the side often coexists with attacks of palpitation, and then the sufferer is sure her heart is "affected." Such "reflex palpitation" is commonly met with. Then there is the "tumultuous" or "badly behaved" heart, whose action is never calm, often a simple nuisance to its owner. There is, too, disturbed action of the heart from indigestion. Then the heart's beat may be slowed by the action of the "inhibitory" fibres of the vagus

nerves, or hastened by some action of the "accelerator" fibres. In the latter case the heart may run off suddenly at the rate of 200 per minute for some hours, ceasing as rapidly as it began. The opposite condition is also present at intervals in some cases, though more persistent in others. Great disturbances of the heart's action, which is often markedly enfeebled, are found with latent gout, usually relieved by an attack of regular gout. Then there is the "irritable heart," where, though the condition is truly neural, there is distinct inability to maintain effort. This is the result of much hard work and mental strain combined, and is commonly seen in medical men. There are also the "smoker's" heart and "tea-drinker's" heart, well recognized disorders; truly "toxic" derangements of the heart. Angina pectoris (vaso-motoria) may occur with a heart still structurally sound, or in one where fatty decay is established. In the first, it is of comparatively little importance; in the latter it is fraught with danger to life. The treatment of neural complaints is as different as their nature.

Sir Joseph Fayrer thanked the author of the paper for the lucid exposition he had given of the various neural diseases of the heart. He could confirm much that had been said, and especially the fact that such states were often relieved by treatment which would have done harm to sufferers from organic cardiac mischief.

Dr. Sanson testified to the great prevalence of these maladies. He thought there was some other factor than mere dyspepsia in certain cases of cardiac intermittency. Cases illustrating his remarks were quoted, showing how even single errors of diet in things not usually considered indigestible might produce the disturbance, which was as readily relieved as originated. An instance of fright leading to apparently acute dilatation of the heart was narrated as affording ground for the belief that organic disease might be consequent on a primary neural affection.

Dr. Wynn Williams asked whether uric acid circulating in the blood could produce intermittent action of the heart.

Dr. Isambard Owen thought that those cases where the pulse failed at times to reach the wrist were of very grave significance. He had seen instances of very frequent pulse unassociated with other signs and lasting for months.

Dr. Braxton Hicks gave some facts observed in his own person. Rapidity of pulse and even intermission seemed to be distinctly related to overwork or some mistake in diet of the nature of an idiosyncrasy.

Dr. Fothergill replied in the affirmative to Dr. Williams, and agreed with the remarks of Dr. Owen. If Dr. Sanson had seen mural disease of the heart arise from neural affection, he (Dr. Fothergill) had witnessed the production of valvular changes; and so there seemed but little doubt that these slight affections might lead to more grave diseases. A larger number of observations in every direction was what was wanted.

Large Fibroid Enchondroma of Palate; Excision; Recovery.

Dr. William Stokes reports this case in the *Dublin Jour. Med. Sci.*, November, 1883:

A boy, aged eight, was admitted into hospital, under my care, on February 10, 1879. The child's parents informed me that he had never complained of anything in connection with his throat until about six weeks previously to his admission into hospital, when they observed a sudden change in the quality of the boy's voice. On opening his mouth they perceived a large prominence occupying the greater portion of his palate. The boy was well-nourished and healthy-looking, and had never suffered from anything except the usual infantile diseases. There was no history in his family of scrofula or of cancer. On examining the tumor, I found that it occupied mainly the left side of the palate, and that although it appeared to cross the mesial line, it did not really do so, but merely overlapped it. It was very vascular, and numerous vessels were observed ramifying over its surface. The boy suffered nothing from difficulty of deglutition, nor from any impediment to respiration through the nostril on that side. On passing a Eustachian catheter, no obstruction was found in the pharynx. There was no fluctuation, but the tumor was decidedly elastic, and some portions were considerably denser and harder than others. At certain points I felt distinct, apparently cartilaginous, nodules. There was apparently no adhesion of the mucous membrane to the tumor, as it moved freely over it. On the front of the tumor was a depression occupied by a superficial ulceration; from this there was no hemorrhage at any time.

A point of practical importance in the case was to determine the origin of the tumor—whether, namely, it grew from the base of the skull, from the roof of the nasal fossa, from the hard, or in the soft palate—the nature of the operative procedure having to be determined, to a great extent, with reference to the situation of the tumor, and therefore it was all-important to determine what its origin was. I determined, if possible, to remove the tumor without making any external wound. Accordingly, after opening the mouth as wide as possible by T. Smith's gag, I made a free incision over the anterior aspect of the tumor, and proceeded to dissect the mucous membrane off the tumor. This being done, and no adhesions being found, I was enabled to pass my finger round it, and eventually succeeded in enucleating and removing it. I found that it had no attachments to any of the neighboring osseous structures. The absence of any difficulty in passing an instrument down through the nasal fossa was chiefly the reason that made me come to the conclusion that the tumor had not its origin from the base of the cranium; but I did think that it was possibly attached to the palate or superior maxillary bones, in which case I should have had to split the hard palate, and arrive at the tumor in that way. I found, however, that it was essentially in the soft tissues of the palate itself, and, in fact, lodged in its substance.

On making a section of the tumor after its removal, I found its substance to be very firm, consistent, and elastic, and rather more dense towards the centre than the circumference. For a short time after the operation there was very sharp hemorrhage, but this was checked by pressure and cold, no vessel having to be ligatured. The wound rapidly united. In examining the

tumor I had the assistance of the late Dr. R. Harvey. The tumor was composed of fibrous tissue over a cartilaginous matrix. The greater portion of it might be described as a fibroid enchondroma. It had also, Dr. Harvey stated, "masses of round cells, evidently of recent growth, and of a more or less sarcomatous nature."

There has been no evidence of any recurrence of the tumor.

Epithelioma of Cervix Uteri—Recovery without Operation.

The *Medical Press*, September 12, 1883, says: Cases of the above have been recorded from time to time, and upon perusing the reports of such cases carefully, one can scarcely arrive at any other conclusion than that if actual recovery does not take place, such a degree of improvement does that we can scarcely blame the fortunate attendant for designating the result as recovery.

It has long been observed that under certain circumstances, such as high general pyrexia, as in the case under notice, erysipelatous inflammation around the affected part, other inflammations, such as that produced by the injection of irritants in the vicinity of the diseased portion (Duploux), or like that produced by the actual cautery in the affected mass (Gallard), or around it (Nussbaum), a normal cell growth may, and occasionally does, take the place of the abnormal growth characteristic of cancer.

Such a case has been recently reported in the *Deutsche Med. Zeitung* by Dr. Staffhorst, of Otten-dorf, Hanover. There appears to be no reason to doubt the accuracy of the diagnosis. The case was under observation several months; it resisted every method of treatment, the patient going almost steadily from bad to worse; and it was not till an unexplained attack of pyrexia, preceded by violent rigors, occurred, that any improvement took place. It might be supposed that the pyrexia was due to an attack of pelvic cellulitis, or peritonitis, and that this in some way modified the cell development of the diseased portion; but the report appears to negative this supposition. No mention is made of pelvic inflammation, and it is scarcely likely that such a complication should have remained undiscovered, or that no mention should have been made of it had any been noticed. Whatever the cause may have been, the progress of the disease seems to have been arrested immediately after the occurrence of the pyrexia: the hæmorrhages and offensive discharges ceased, and in the course of a few weeks the ulcerated surfaces were covered by cicatricial tissue. Some shortening of the vagina had taken place, posteriorly the cervix had become attached to the vagina, and some tenderness remained in the hypogastrium, especially after long standing. The patient's appetite was good, and she had increased in weight and strength, so that up to the date of the report, four months after cicatrization, the improvement promised to be permanent. Upon the whole, we may conclude from the report of this case, taken in conjunction with expressions by other recent writers, that the prognosis in any particular case is not absolutely unfavorable, and it remains for us to follow up the faint glimmerings of hope that are here and there vouchsafed us.

REVIEWS AND BOOK NOTICES.

BOOK NOTICES.

A Treatise on Pharmacy. By Edward Parrish. Fifth edition, enlarged and thoroughly revised by Thos. S. Wiegand, with 256 illustrations. Philadelphia, H. C. Lea's Son & Co., 1884. 1 vol., leather, 8vo., pp. 1088.

The art and business of the pharmacist have materially changed since the first edition of the above standard work was issued, and the enlargement of its size and extensive additions to its contents are a fair index in the rapid growth of the pharmacist's profession. We say "profession" because, when one surveys the extended, varied, and minute scientific knowledge essential to the full appreciation of this book, it is evident enough that the student of pharmacy has to pursue a course of study quite as recondite, quite as elevated, quite as remote from "business," as has the student of medicine, of law, or any of those vocations hitherto distinguished as "professions."

Thus, much the larger portion of this treatise, to wit., from page 170 to 640, is devoted to chemistry, inorganic and organic, in its relation to pharmacy, and can only be understood by one who has already mastered more than the elementary principles of that difficult science. Introductory to this portion is a chapter on pharmaceutical processes and apparatus, and following it are two parts, one on "Galenical Pharmacy," the other on "Extemporaneous Pharmacy." The last mentioned are what in an older generation would be considered about all that a druggist need know.

This new edition has been required, partly by the constant additions to pharmacy, and more especially by the late revision of the U. S. Pharmacopœia. The changes have been considerable, involving, among other things, the rearrangement of the entire chemical section in conformity with the present views of that science.

The paper, printing and binding of the book, and the character of the illustrations, leave nothing to be desired in those directions, and we can point to this volume as one eminently creditable to the author, the editor, and the pharmacy of America.

Conférences de Clinique Médicale faites à l'Hôtel Dieu. Par M. le Dr. F. Raymond, Paris. A de la Haye, 1883. 8vo., pp. 248.

Dr. Raymond presents his readers with a varied assortment of cases from his most recent hospital service. There are in all fourteen conferences, each

treating of a different class of cases. Beginning with sarcoma of the uterus and of the dura mater, he takes up in turn abscesses of the ear, meningitis, acute myelitis, chronic pneumonia, articular rheumatism, especially in its pulmonary and cardiac complications, muscular atrophies, cerebral syphilis, cirrhosis and icterus, aneurism of the aorta, latent cancer of the stomach, neurones, and nephritis.

His method is the strictly clinical one. Every conference takes for its text the actual patient. His present condition is studied, his past history is searched for, and on these factors are constructed the diagnosis, prognosis, and treatment. The general relations of the case are then explained, and the value of various therapeutical measures discussed.

We regard the volume as a good specimen of French clinical lectures.

La Longevité et les Moyens de l'Acquerir. Par Joseph G. Richardson, Professor d'Hygiène à l'Université de Pennsylvanie. Traduit par P. Barrué, Paris. Asselin et Cie, 1884.

The growing respect for American medicine abroad is illustrated in many ways, and in France notably by the publication of a "Collection Américaine" of a series of volumes translated from works of our own medical authors. That whose title is given above is by Dr. Richardson, of Philadelphia, and is a translation of his essay on "Longevity," which has already achieved considerable popularity in our own country. All the questions relating to this always interesting topic are discussed in a lucid and attractive style, and the public interest in sanitary topics is thus secured by holding out to them the coveted reward which they can probably gain by obedience to the precepts of health.

We have examined the translation in a number of passages with care, and have found it very well done. M. Barrué has a simple and effective style, and his knowledge of English is evidently thorough.

Such a recognition of the merits of a volume is not merely creditable to the author; the credit is reflected on the medical profession of our country generally, and such appreciation of our best medical literature abroad will be felt by all in a greater or less degree.

—To attain length of days maintain a mental equanimity which neither success nor reverses can disturb. Love nothing too passionately; hate nothing too violently; fear nothing too strongly.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

THE COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

LITHÆMIA.

Whatever may be the cause of the condition commonly designated "Lithæmia,"—whether it be allied to gout and is really, as some maintain, a "suppressed gout"—matters but little to the practical physician, since we have the means at our command of relieving it. The etiology is of course interesting, and we trust that the labors of our clinicians and scientific workers will be crowned by an elucidation of this debatable question; but what the busy doctor more particularly requires are the points of diagnosis and treatment.

It is particularly essential that we should be prepared to recognize this affection, since it so often simulates serious organic disease; and yet, if understood and properly treated, very simple measures will produce exceedingly happy results.

Oftentimes a patient will come complaining of vague, ill-defined bad feelings, which make him apprehensive of kidney or heart disease, or of impending serious trouble. A careful examination fails to reveal any organic disease; for, says Dr. George H. Lyman, in the *Boston Med. and Surg. Jour.*, December 13, 1883:

"The disorder in question has no fixed set of symptoms. The subjective expression of the pathological condition may manifest itself in protean forms. Either the gastric, rheumatic, renal, hepatic, cerebral, or cardiac, or several of them combined, may seem to predominate in any particular case, yet each is dependent in great measure upon certain lithuric conditions, which being neglected, render any treatment unsatisfactory if not wholly useless. It is not necessary that nausea, constipation, or diarrhœa, headache, insomnia, or palpitations, myalgic pains, or urinary deposits, should all be present in any given case; the subject of it indeed is quite likely to express himself as being otherwise in good health and strength, vigorous in mind and body, and yet so tormented at times, and apparently without cause, with one or more of the functional nervous phenomena described, as to induce in him the fear of some fatal organic defect of heart or brain.

"Of the varied symptoms, none are more distressing than the two which are the more immediate subjects of this paper: a constant tinnitus aurium from which there is no escape during the waking hours, and indeed which often interferes with the sleep—buzzing, ringing, clicking, or

constant pulsation, for which no visible nor tangible cause can be discovered either in gastric disorder or the external and internal auditory apparatus—is not only a constant source of annoyance but of serious apprehension to its unfortunate possessor; or still more if either with or without this tinnitus the victim finds himself the subject of sudden attacks of vertigo, so severe and decided as to cause a staggering gait, possibly complete prostration, as an attack of epilepsy, the case assumes a gravity which startles and terrifies its subject into fear of impending death.

"Another will have renal complications dependent wholly upon some hepatic derangement of function, which sends him from one physician to another in the hope of relief to his fear of Bright's disease, diabetes, or cystic calculus, while still another may be complicated solely with tormenting muscular or arthritic pains. And so on, one might recall instances of one or more of these, with the addition of purely nervous complications, simulating to the fears of the patient almost every conceivable organic disease."

Dr. Lyman seems well satisfied that this condition is due to faulty assimilation, this in turn being produced by dietetic errors.

He relates a most interesting case of a physician, who, after indulging in certain articles of diet, would be invariably attacked with tinnitus and great mental confusion. By avoiding that which he learned by experience to be hurtful, he could remain absolutely free from these attacks. Herein lies the principle of treatment. No definite, dogmatic dietetic laws can be laid down, each case must be a law unto itself, but certain rules can be enunciated.

That the liver may rest from its overcharged labor, saccharine, nitrogenous and alcoholic ingesta must be diminished, both sedentary habits on the one hand, and excessive fatigue on the other, and over cerebral exertion from study or worry, avoided, they all tending to weaken the circulation, and so favor acid accumulation.

With regard to the use of tonics, mineral or vegetable, they are often worse than useless, especially in the early stage of average cases, in which, with a careful diet, mild saline laxatives perseveringly used are the best tonics. In anæmic or broken-down cases their use may be, of course, a necessity.

In most cases alkaline salts are indispensable, and citrate of lithia is as useful as any, and perhaps the most agreeable to the stomach, although occasionally it over-stimulates the kidney and must be suspended for a time, or replaced by soda or potash, taken an hour after meals, these being in all cases preferable when much flatulence is complained of. Salicylate of lithia might be tried.

Where the pain is myalgic, muriate of ammonia in full doses will often give prompt relief, though if this result does not follow within a day or two, its continuance is useless.

Dr. Lyman lays great stress on the use of aperient bitter waters, such as Hunyadi or Pullna.

The patient should always be made to understand that the relief which he may receive is to be permanent only so long as the conditions of the cure are complied with, and that any indulgence or excess will almost inevitably be followed by its penalty; and moreover, remembering that too frequent recurrences of merely functional disorder are likely to result eventually in actual organic changes no longer amenable to curative treatment.

During the discussion which followed the reading of this paper, Dr. Webber said that two symptoms had not been mentioned which are not so frequent, perhaps, as the others, but are yet of interest—irritability of temper, or a change of disposition; this may be only an accidental coincidence, depending in part upon the annoyance and discomfort caused by the other symptoms; perhaps, however, it may be due to the deficient nutrition of the brain. These patients are often much more disturbed at certain times in the day than at others, are excitable, and sometimes violent. Another symptom is temporary deafness, which may last only a few hours.

The diagnosis between lithæmia and other nervous affections is by no means always easy. Two conditions or diseases may be thought to be present, namely, tumor of the brain and epilepsy, when there is only lithæmia. A patient with headache, tinnitus, vertigo, change of disposition and languor, may be suspected of having a tumor; even a careful examination may not satisfactorily clear up the doubt, and it would be necessary to

wait for time to show the truth by the development of other symptoms, or by the recovery of the patient.

Therefore, when a doubtful and seemingly inexplicable case of departure from health, simulating organic disease, presents itself, it will be well to bear in mind this instructive article of Dr. Lyman's, and to remember that the therapeutic powers of diet have yet to be developed, that we know very little about them. One of the most interesting fields for the general practitioner to labor in, and one that is so rich in possibilities, because it is so little worked and so sure to make great returns, is the field of diet. What influence has it in causing disease, and what power has its regulation in restoring the functions to a healthy standard? That it has much more influence on the health of mankind even than is to-day accredited to it, we have no doubt; and with the growing tendency to rank preventive ahead of curative science, no subject can be more worthy of careful consideration, than the preventive and curative influence of diet.

WHAT IS LEGAL PROOF OF PROFESSIONAL SERVICES?

An important opinion touching the business interests of physicians was recently delivered in this city in the Orphans' Court, by Judge Ashman. The question arose on exceptions to an adjudication in the estate of Clarence J. Gorman. The physician to the decedent had rendered to the estate a bill for professional services, which had been contested on the ground that it was excessive—that there was no evidence that the visits had been rendered, and that the fees claimed were excessive. The question was referred to an auditor, who took testimony. The physician relied chiefly on a pocket visiting list (not that one published through the office of this journal), but the auditor threw out that record as an insufficient one, and not up to the legal requirements of the case. Exceptions were taken to his ruling, and argument was held before Judge Ashman. On account of its great importance, we quote the judge's opinion in full:

"The rule of evidence which introduces a tradesman's books of original entries to prove his sales is permitted to override the principle that a party may not manufacture evidence for himself, on the ground of convenience. It cannot be said to have been dictated by necessity, because in England, where these books serve only as memoranda from which the party producing them may refresh his memory, it has been found, according to Mr. Best (*Best's Evidence*, 853), that all the advantage, without any of the danger, incident to this character of proof, is obtainable. For the reasons which justify its use in the case of a merchant, it has been so far extended as to embrace, perhaps, the books of any person whose business is not in money, and is of such a nature that its transactions can be itemized with the precision with which a sale may be recorded. It is perfectly consistent with this broad statement that a doubt should have been expressed in *Hale's Executors v. Ard*, 12 Wr. 24, whether the books of an attorney containing charges for advice are evidence. Such entries, as was there said, must be incapable of certainty in description, because the services themselves are indefinite in their nature, and can neither be gauged by the time they occupy nor compared with other similar services with which a jury is supposed to be acquainted. But this objection can scarcely be said to apply to the record kept by a physician. It may cover a daily entry of each visit, with the name of each patient, a list of the medicines furnished, and the price which custom has fixed for the particular service. Such a record will comprise all the incidents of certainty of time, person, labor, and value, and each entry will be complete in itself. No more than this is required in the books of an artisan, and the measure of necessity is at least as great in the one instance as the other. If the proposition has been correctly stated, it affords an easy test of the validity of the proof submitted by the claimant. His diary, or visiting list, as a physician, contained on each page a list of names of patients, with tally marks opposite, in columns which were headed separately with the days of the week, the name of the month appearing at the top of the page, and the date of the year on the cover. One column at the end of the space for each week was headed 'amount.' Preceding these lists as a sort of preface to the book, was a 'Table of Signs.' This table embodied a series of hieroglyphics and figures, which were intended to denote visits made and to be made, and visits repeated or to be repeated; consultations proposed or made; services at the office; visits at night;

medicines furnished, etc. It is quite clear that entries patterned after this fashion could serve, at best, only as memoranda from which to make more formal charges. As original entries, even if decipherable, they were incomplete, because their form admitted only of a weekly charge in money, and in point of fact no charge at all appeared to have been made. Allowing the utmost latitude to the plea of convenience and necessity, the law cannot tolerate as self-proving an entry of services which can be translated only by means of a glossary. Such a writing would be as unintelligible to an ordinary jury as a Hebrew Bible to a deputy sheriff. The auditing judge, therefore, properly threw it out of the case. The sum which he finally awarded to the claimant, we think, was all that was shown by the oral testimony to be due.

"The exceptions are dismissed and the adjudication is confirmed."

We are not aware that this point has been covered by any decision of the Supreme Court. But it is at least very doubtful if the higher tribunal would reverse the above opinion. It will be prudent, therefore, for physicians who intend to carry into court their claims for professional services, to prepare themselves to meet the position above taken by the auditor and the judge. They must keep such a system of records as shall meet the demands of the principles of commercial jurisprudence above laid down.

NEW MEDICAL COLLEGES.

A somewhat surprising bill was introduced a few days ago in the United States Senate by Senator Call. It contained the magnificent project of establishing a medical college in Washington with a permanent endowment of one million dollars! This sum, we suppose, was to come from the plethoric purse of the central government. If the government is going into this sort of business, a medical college is as good as anything else to establish: but Washington is no place for it. Nor has it been generally supposed that it is part of the functions of our government to start colleges for professional education. As the full bill has not reached us, we merely make this passing comment on this extraordinary fact.

New York papers state that the Regents of the

University at Albany have refused a charter to the United States College of Medicine and Surgery of New York city. It apparently impressed itself on the Regents that a multiplication of colleges must lead to a deterioration of the course and facilities of medical study. It is true that competition is a positive advantage up to a certain point; but beyond that, it is sadly deteriorating. An instance of the latter was lately shown by a medical college in Louisville, Ky., which distributed a circular to the first course students of its neighbors, advocating its own merits, and offering its cheapness and the like, in a manner savoring of the lowest arts of a Bowery Cheap John establishment.

From a letter before us we have been favorably impressed with the prospects of the medical college lately established in Quincy, Illinois. That city is a thriving and beautifully-located railroad centre on the Mississippi. The inhabitants are about 35,000 in number, and its hospitals and clinical facilities are unusually ample for a place of that size. The general educational advantages there are exceptionally good, and its central and accessible location is much in its favor. The faculty of the college are chiefly resident physicians and surgeons, some of whose names are widely and favorably known in medical literature. We wish it every success.

NOTES AND COMMENTS.

Notice the Date.

Subscribers will oblige us by taking note of the date which they will find on the printed address on their REPORTER or its wrapper. This date shows the time up to which they have paid. It serves as an acknowledgment of the receipt of remittances. It also shows when the subscription is due; and we would earnestly ask those who find that this is the case, to remit us at once, as prompt payments relieve us from much correspondence, and the unpleasant necessity of personal reminders.

To Abort Mammary Abscesses.

Dr. James Braithwaite writes to the *Lancet*, December 15, 1883, as follows: *will be found in*
 "In cases of threatened mammary abscess, I
in which he says

have for many years, with very successful results, given three consecutive doses of ten grains of quinine at intervals of twelve hours, at the same time using the usual local application of belladonna. The administration of quinine in these cases, although its anti-suppurative power is well-known, is not practiced by any one with whom I have conversed, but I have myself found it so successful, that I think it deserves to be in general use, especially as the disease is so painful and so exhausting to the system. The best cases for the treatment are those occurring during lactation, and it is less suitable immediately after labor. It is unsuitable if the bowels are confined and the tongue furred. There are some patients who do not bear such large doses of quinine, in which case a first dose of ten grains may be followed by two of five grains each. I originally saw this treatment recommended in a French medical journal, and claim therefore no originality. I have frequently seen the pain and tenderness disappear within forty-eight hours, although a little hardness will remain for some days or longer, and the inflammatory symptoms may recur, and may be again at once checked by the same treatment. A recurrence, however, is rendered less likely if the belladonna is continued for a time, although pain has ceased. No doubt some will say that the success of the treatment is owing to the belladonna, and not to the quinine. I used the belladonna for years before I used the quinine in addition, and was struck with the greater rapidity and certainty of the result when the quinine also was used. At the same time I admit the difficulty, when two drugs are employed, of apportioning to each its real value."

Albuminuria and Phthisis.

Without going into details of the excellent papers which Dr. C. Theodore Williams has contributed to the *Brit. Med. Jour.*, December 22 and 29, 1883, it will be interesting to note that he considers the prognosis unfavorable when albuminuria appears, for he says:

"A careful study of our cases will disclose a very unfavorable outlook for the complication of albuminuria with phthisis. The patients died generally within a few months of the appearance of the first symptoms—one after a few weeks; and the longest case lasted but three months. Private patients, however, appear to live longer, and I know of some cases where life has been prolonged even for years. In the discussion on Dr. Sparks and Dr. Bruce's paper read before the

Royal Medical and Chirurgical Society on January 14, 1879, on the Effect of Diet and Rest in Chronic Nephritis, Dr. Quain cited a case of phthisis of fifteen years' standing, with albuminuria of five years' duration; and one of extreme albuminuria and extensive chronic phthisis, with but little influence on the general health. In one of my patients who has had phthisis for fifteen years, and a considerable-sized cavity for ten years, albuminuria supervened six years ago, and he still survives, although in a very precarious condition. Another patient, of twelve years' duration, has had slight albuminuria for one year, and is still able to travel, though living the life of an invalid. These are the longest cases I can recall; and they must be regarded as the exception, and not the rule. Many others whom I have seen have sunk a few months after the albuminuria set in; so that this symptom must, in all cases of phthisis, be regarded as of very serious import."

Poisoning by Bryonia Dioica.

Dr. S. B. Mason thus writes in the *Brit. Med. Jour.*, December 1, 1883:

"About two weeks ago, I was hastily summoned two miles in the country to see a child, aged 4 years, supposed to be suffering from eating some red berries given by children while at play. From the description given by one of the children, I came to the conclusion that the child had eaten berries of the red bryony. On examination, I found the child apparently in great pain in the abdomen, very thirsty, hot, and excited. With some difficulty I administered one scruple of powdered ipecacuanha, with ten grains of sulphate of zinc, in warm water. In due course this produced copious vomiting, together with a free action on the bowels. I waited about twenty minutes, and as no further vomiting occurred, and the pain in the abdomen continued, I repeated the emetic. This excited the vomiting again. The first vomit contained portions of about a dozen berries, the second about half that number; and one or two ejections in the course of the night simply contained fluid colored with the juice of the berry. The child was put to bed with a warm poultice over the abdomen, and some senna-tea administered, which operated freely, bringing away several skins of the berries. On the following day the pain had ceased, but the temperature in the axilla was 103°. A saline mixture was given, and for the next three days the temperature kept up, but, after that time, gradually subsided, and the little fellow recovered his normal

state of health. On first seeing this case the pulse was very feeble, but, after the vomiting, it increased in power wonderfully."

Nutrient Enemata in Reflex Vomiting.

Reflex vomiting from a uterine cause had reduced to a condition of extreme exhaustion a patient, about whom Dr. Quinlan writes in the *Lancet*, December 15, 1883.

The nutrient enemata employed in this case consisted of two ounces of very good beef-tea with one of milk. To these fluids mixed together and heated to 120° F., a teaspoonful of Benger's pancreatic fluid was added, and the whole was allowed to remain under a cosy for twenty minutes. A dessertspoonful of brandy was now poured into the enema, which was administered blood-warm. In using these nutrient enemata, whether of beef-tea, milk, or eggs, it is not always remembered that the large intestine has no peptonizing apparatus for rendering colloid substances dialyzable. As a consequence they do not pass through the mucous membrane, and a feeling of distension is experienced, often ending in the expulsion of the remedy. A peptonized enema causes no feeling of distension, or at least one that soon passes away; and any patient who has tried both ways will at once tell the difference. Sometimes in prolonged enematisation the bowel becomes very irritable, and in this case the addition of a little opium (if the other symptoms do not contra-indicate it) is most valuable. It is hardly necessary to add that nutrient enemata should not as a rule exceed four ounces. It is better to repeat them often than to run the risk of expulsion attending the use of larger ones.

The patient's strength was thus maintained until the gastric irritability subsided.

A Convenient Way to Stretch the Sciatic Nerve.

In the course of his paper on "Nerve-stretching for the Relief or Cure of Pain" (*Lancet*, December 15, 1883), Dr. John Marshall says:

"Before concluding I must ask you to bear in mind that the cutting operation to which I have alluded hitherto, is not the only way of stretching nerves, for it has been found in case of the sciatic that if you bend the thigh upon the body, so that the knee comes up to the chin, and then straighten the leg upon the thigh and flex the foot upon the leg so as to stretch the ankle-joint also, you can produce an extraordinary strain and tension upon the sciatic nerve as it passes out of the pelvis. Trombetta, who is a great advocate

for this method—Billroth has the credit for introducing it, but I believe Trombetta was earlier—found that the sciatic nerve in the dead body could be stretched one inch by this proceeding; but the proceeding must be tolerably firm and resolute, and I would say, in order that it should succeed, it should be continued for five minutes. That is the sort of rule I would lay down in all these cases. Mr. Horsley has stretched the sciatic nerve on the dead body in this way, and has found that it does diminish the diameter of the nerve."

This method should be tried in obstinate cases of sciatica.

Experiments with the Sputa of Phthisical Patients.

A foreign contemporary tells us that M. Vignal has been trying some experiments with the view of ascertaining whether the sputa of phthisical patients as found in the streets still contained bacilli. He collected a certain quantity of such sputa and submitted it to desiccation; he then moistened it and let it dry again at different times, so as to place it as much as possible in the condition in which it would be found in ordinary circumstances in a room. He discovered that the sputa thus treated contained bacilli as numerous and as well formed as if they had just been expectorated. He inoculated two guinea-pigs with the matter; one of which died in a few days from obstruction in the bowels, and he could not in consequence come to any conclusion; but the second animal, though it increased in weight during the first few weeks subsequent to the injection, afterwards began to lose flesh, and died in about three months. At the autopsy it was found that in all the organs there were a great number of tubercles which contained bacilli. M. Vignal concludes that sputa of phthisical patients, as found on the ground, in the streets, or in apartments, are far from being inoffensive, and might become agents of contagion to persons predisposed, or in whom the bacilli would find a favorable soil for propagation.

The Medicinal Properties of Arlentin.

The *London Med. Rec.*, December 17, 1883, says: Arlentin, the alkaloid of uva ursi, is a potent diuretic, and, according to Dr. Mensche, becomes converted into hydrochinon and sugar by boiling with acids, or under the influences of fermentation. Dr. Mensche (*Centrabl. für Klin. Med.*, No. 27, and *Centrabl. für die Med. Wiss.*, September 29), gives the following as the results of his observations upon the action of this alkaloid: 1.

In many cases it has proved to be a valuable diuretic. 2. It may be given in large doses without detriment. 3. It becomes converted into hydrochinon in the human urine. Its action as a diuretic was noted in two cases; in one, a case of mitral insufficiency, enlarged liver, and albuminous urine, the quantity of urine was augmented by about four ounces in twenty-four hours. In another case (tubercular peritonitis) the quantity of urine was augmented by about six ounces daily. In another instance the amount of the excretion was doubled under the influence of arlentin. This medicine has, however, Dr. Mensche reports, a specially beneficial action in vesical catarrh; and he suggests its employment in the place of uva ursi. In gonorrhœa, the author considers that it may supersede the use of injections by its conversion in the urine into hydrochinon.

Cause and Mechanism of Flat-foot.

The *Med. Times and Gaz.*, December 29, 1883, tells us that Dr. Hermann von Meyer, Professor of Anatomy in Zürich, after a careful examination of the normal and of the flat-foot, anatomical as well as clinical, comes to the following conclusions, which, as will be seen, are somewhat at variance with the generally accepted views: Flat-foot does not depend on destruction of the arch of the foot, but on a valgus position of the foot, and chiefly of the os calcis, with regard to the astragalus, together with, as a complemental and secondary condition, version upwards and outwards of the fore part of the foot. The deformity is not due to relaxation of the plantar ligaments, but depends rather on exaggerated rotation inwards of the astragalus, and on subsequent changes in the conditions of the plantar bones, due to the atrophy resulting from mutual pressure. The present brochure ("Studien über den Mechanismus des Fusses," part 1, published at Jena) is the first of three in which the normal and pathological conditions of the foot are to be discussed. We shall look forward to the others with some interest; the second will deal with the normal mechanism of the foot, and the last will complete the subject by discussing the various forms of club-foot.

Iodoform in Obstetric Practice.

The germ theory of puerperal diseases has called into vogue the treatment by germicides, which really constituted the essence of the treatment recommended by Dr. Thomas, to which we recently referred. In this connection, we note that Ehrendorfer (*Arch. f. Gynakologie*) has had

good results, in a limited number of cases, where, in, on account of instrumental delivery or other causes, infection was to be feared, from the use of iodoform. The method employed was the following: The uterus, after the expulsion of the placenta, was washed out with a solution of carbolic acid (one per cent.), and then a bougie containing five to ten grammes of iodoform was pushed into the uterine cavity beyond the inner orifice, and allowed to remain there. No vaginal injections were used afterwards, and only in seven cases was a second bougie introduced. This method was employed in twenty-seven cases; of these three died, and two were transferred to other parts of the hospital. There were but two cases of natural labor amongst the number; the rest were cases in which operative interference of some kind had been necessary, or cases of abortion with retained placenta.

Corrosive Sublimate in Phthisis.

Growing out of Koch's demonstration that corrosive sublimate is fatal to the activity of the tubercle bacillus, Dr. E. P. Brewer, of Norwich, Conn., writes to the *Med. Record*, January 5, 1883, that he has devised an apparatus for its use in phthisis, which he thus describes: He uses oxygen as a medium for carrying this drug into the lungs. The apparatus consists of a tank holding one hundred and twenty gallons of oxygen at a pressure of one hundred and twenty-five pounds per square inch; a wash-bottle and a drying-bottle, such as are ordinarily used for washing and drying gases. Finally, a metal receptacle holding eight ounces and heated by a lamp. In this receptacle is placed a solution of corrosive sublimate 1 to 800 or 1,000, and heated. The oxygen passes through the washing and drying-bottles, then through the hot and partially vaporized solution of corrosive sublimate. It then passes out through a rubber tube and is inhaled. Dr. Brewer is not yet prepared to report upon the practical results achieved by the use of his apparatus.

Poisoning by Jequirity.

From the *London Med. Record* we learn that Dr. Lagleize was called to see a youth, aged 19, who presented the following symptoms: The face was swollen, the eyes staring; there was great salivation, as after an injection of pilocarpine; the pulse was small and weak (180 to the minute), the skin dry, the extremities cold. While he was wondering what could have given rise to these symptoms, Dr. Lagleize noticed on the ground

some little seeds, which, on picking them up, he recognized as the seeds of jequirity. On interrogating the family as to whence they came, he learned that a friend, recently arrived from Brazil, had brought them as curiosities. As the symptoms were somewhat like those produced by pilocarpine, he administered an emetic of ipecacuanha, and afterwards sulphate of atropine in a mixture, and applied warmth to the extremities. The patient soon recovered, and the next day was pretty well.

SPECIAL REPORT.

NO. XV.—OPHTHALMOLOGY.

BY C. S. TURNBULL, M. D.,

Oculist to the German Hospital, Philadelphia.

From the Progress of Ophthalmology During the Second and Third Quarter of the Year 1882, by H. Magnus, of Breslau, and Others.—Archiv. Ophthalm., vol. xii., No. 1.

[Translated by Dr. F. E. D'OENCH, New York.]

The Influence of the Slanting System of Penmanship upon the Eyes of Children. Bay. *Ärztl. Intelligenzblatt*, vol. xxix., No. 21, 1882. Schubert insists upon placing the book parallel to the table's edge, and would exclude the inclined system of penmanship entirely from the schools, as the difference in the distance of the two eyes from the point of fixation produces unequal accommodation, which may easily lead to the loss of binocular vision; and further on, to difference in refraction and visual power, and, finally, to squint.

Berlin denies these conclusions. The act of writing is controlled by the eye, in particular by the laws which govern the movements of the eye. As the downward stroke is always perpendicular to the base line, it must cross the latter, when writing with letters inclining to the right, from the left side and above to right side and below. The consequence is, that when the book lies straight the child must sit inclined to the right, may sit straight when the book is placed obliquely, and when this position is exaggerated, must sit inclined to the left. The inclined system of penmanship, when the book is placed obliquely, has this advantage over the vertical system, inasmuch as it requires much less muscular exertion, the vertical system calling all the muscles of the arm up to the shoulder into play.

Ophthalmoscopic Examination of the Eyes of 150 New-born Children. Nagel's Commun. from the

Ophth. Clinic at Tübingen, vol. iii., p. 144. Schleich found the eyes of the new-born to be hyperopic, the same as Königstein, Horstmann, and Ely. According to the observations of Albrecht, the degree of refraction was the same in both eyes in forty per cent. of 1,638 cases examined. In 50.6 per cent. of 940 cases, the result of the examination of both eyes was the same with the ophthalmoscope as with glasses; in the remainder there was a difference. Out of 1,120 cases there were 417 with high degrees of myopia, *i. e.*, more than 6 D. 41 (10 per cent.) of these showed no traces of atrophy of the choroid, or sclerectasia. Cases were also observed in which an increase of the degree of myopia without convergence or accommodation could be demonstrated.

Studies Over Myopiers Etiologi. Copenhagen, 1882. Tscherning draws his conclusions from the observation of 9,567 persons. He distinguishes three kinds of myopia:

1. Myopia from unknown causes, not due to close vision or diseases of the eye, perhaps to hereditary predisposition. This kind of myopia is either congenital or develops up to the age of twenty-five. The fundus is normal; there is either no conus, or only a very narrow one. Vision is generally good. As a rule, only the lowest degrees of myopia belong to this category.

2. Myopia due to too near vision is most common among the educated classes. It is less than 9D.=4 $\frac{1}{2}$ ''; on an average it about equals 4D.=9 $\frac{1}{4}$ ''. Sometimes there is a congenital predisposition. The anatomical changes are not yet sufficiently known. It is rarely complicated with choroiditis, but the conus is common.

3. Excessive degrees of myopia (more than 4) are governed by another law in their distribution. They are found in all classes of society, without regard to their occupation; they must be regarded as a genuine disease, and are comparatively rare, scarcely in more than one per cent. of the population.

This form of myopia is always due to an elongation of the globe, and is generally complicated with other diseases of the eye, especially of the choroid. It is probably a chronic form of choroiditis, with exudations into the vitreous.

Cases of Unusually High Degree of Accommodation Spasm, Myopia Simulated by Hypermetropic Eyes. Med. News, May 6, 1882. Harlan reports three cases of spasm of accommodation, in which myopia $\frac{1}{2}$ resp. $\frac{1}{3}$ was found before using atropine, but afterward hypermetropia $\frac{1}{8}$ resp. $\frac{1}{3}$ and $\frac{1}{2}$.

Sudden Paralysis of Accommodation Completely Re-

stored in a Week. No specific cause. Ophth. Rev., Vol. 1, May 1882, p. 183. Griffith reports recovery from paralysis of accommodation in course of a week, after the use of quinine and strychnine.

Five Lustra of Ophthalmological Practice. Page 274. Mooren mentions the rapid fatigue of the ciliary muscle after severe illness, in sensitive women and onanists. He saw sudden spasm of accommodation develop after injuries in the ciliary region, also in uterine diseases and long-continued close vision.

Une Nouvelle Operation du Ptosis. Ann. d'Ocul., vol. lxxxviii., p. 29. Wecker describes a new method for ptosis, which consists in a combination of that of Pagenstecher and Gräfe. As in Gräfe's method, an oval piece is cut out of the skin and orbicularis muscle of the upper lid, after which two sutures are applied, similar to Pagenstecher's method, one in the inner, the other in the outer part of the lids. The needle is introduced over the inner part of the eyebrow, a finger's breadth above the orbital margin, passed downward under the skin and muscle, out again at the upper margin of the wound, under the edge of the excised orbicularis muscle, entered again under the edge of the orbicularis muscle of the lower margin of the wound, and passed along under the skin of the marginal part of the lid, and then back again, so that the points of entry and exit of the needle are above the eyebrow, about $\frac{1}{2}$ mm. apart. The two ends of the thread are then tied over a little roll of leather. In the same manner a thread is passed through the outer part of the eyebrow and lid. When the threads are tied, the edges of the wound are brought in contact, and should heal by first intention. As soon as the threads have cut through the skin at the margin of the lid, they are removed.

D'Une Modification Apportée au Procédé dit de Transplantation du sol Ciliaire. Arch. d'Ophth., vol. ii., No. 3, p. 208. Panas modifies the method of Anagostaskis in transplanting the lashes, by detaching the flap of the skin as far as the margin of the lid, leaving it only connected with the conjunctiva, then severing the orbicularis muscle and pushing it upward. He then unites the flap with the ligamentum-tarsi-suprius.

On the Treatment of Entropium and Trichiasis by a New Operation. Liverpool Medico-Chir. Jour., July (1882), p. 319. In operating for entropium and trichiasis, Williams makes Burow's incision of the tarsus from the conjunctival side, passes sutures to the outer side, as in the operation of Anagnostaskis and Snellen, and ties the thread on the external surface of the lid.

Del Autoplastic Palpébrale par le Procédé de Gayet. Ann. d'Ocul., Vol. lxxxviii. p. 132. Dianoux operates for entropium as follows: He makes an incision parallel to the margin of the lid, four mm. from its edge, passes Guerin's double-edged knife into the margin of the lid behind the lashes, and thus divides it into an anterior and posterior plate. He forms a strip of skin containing the lashes, and another three mm. broad above the first incision, draws the upper strip under the lower, and fastens the former in the position of the latter.

Ectropion Cicatriciel de la Paupière Intérieure. Operation avec Greffe Dermo-épidermique. Gazette d'Ophth., No. 11, 1882. In cicatricial ectropium of the lower lid, Carré cuts the cicatricial tissue, makes the lid movable, and freshens the edges of the lid. Flaps without a pedicle, which do not extend through the whole thickness of the lid, and then transplanted into the defect.

Weinlechner. The Treatment of Angiomata. Wiener Med. Blätter, 1882, Nos. 38 and 39. Advises to spare the skin of the lid, especially the edge and cartilage, when extirpating an angioma. A plastic operation should not be attempted at once, unless the indications are imperative; but the natural course of healing should be allowed to proceed, and an operation done later if necessary. It is especially difficult to remove the angiomata at the inner canthus. Here Weinlechner tampons the wound with styptic cotton, but does not unite the edges, in order that any remnants may be destroyed with lapis or the galvano-cautery from the wound.

Tumeur Érectile de la Paupière Supérieure Droit Chez un Enfant de 8 Mois. Rev. de Ther., No. 12, 1882. Humbert removed a tumor of the right upper lid of the size of an almond, by injecting a dilute solution of the sesqui-chloride of iron, which only produces a coagulation of the blood similar to that under normal circumstances.

Remarks on Important Cases. Rep. of the Mich. Eye and Ear Infirmary.

Lundy Removed a Varicose Tumor from a Child by Means of Electrolysis. The tumor was situated at the root of the nose, and had involved both eyebrows and half of the left upper lid. A battery with 22 elements was used. The introduction of the needles was followed by considerable reaction. Twelve days later they were again applied; at the end of three weeks scarcely a trace of the tumor was left, and the needles were introduced at only one point. The result was perfect, and only a small scar remained.

Parinaud. Fistule Dentaire Simulant une Fistule

Lacrymale. Journ. des Connaiss. [Med., 1882, No. 36. In a child seven years old, an abscess developed in the region of the lachrymal sac, resulting in a fistula. At the same time there was also a dental fistula of the carious upper canine tooth. Parinaud assumes alveolar periostitis with formation of a fistula, and explains its peculiar position by the peculiar arrangement of the alveoli of the upper maxillary of children. Cured by extracting the tooth in question.

Contributions to the Knowledge of Strabismus. Arch. f. Ophth. Vol. xxviii. 2, p. 97. Schneller reports his investigations on the field of fixation in cases of divergent and convergent squint. It is characteristic of accommodative convergent strabismus that the squint disappears either at once, or after a few days or weeks, when corrected with the proper glass, and that the extent of the field of fixation remains within the normal. Amblyopia of both eyes favors the development of convergent strabismus, though the degree of hypermetropia may be but a low one, also all the factors which tend to diminish the value of binocular vision. Muscular convergent squint disappears under the influence of the proper glass, either at once or after the lapse of a few days or weeks; the extent of the fixation field of the interni also exceeds that of the externi more than under normal conditions. In divergent squint the degree of strabismus is not entirely proportional to the preponderance of the external recti.

In strabismus with normal motility of the muscles, an operation is unnecessary—glasses will suffice; in muscular strabismus an exact examination of the field of fixation must be made in order to find a suitable method of operation. Schneller thinks that the most important result gained by his investigations is the distinction which must be made between refractive, accommodative, and muscular strabismus.

On a Case of Voluntary Nystagmus. Ophth. Hosp. Rep., vol. x., p. 343. Benson reports the case of a young lady of twenty-four who voluntarily could produce nystagmus.

Contributo allo Studio della Paralisi dei Nerve dell'Occhia. Casuistica Clinica. Amd' Ottalm., vol. xi., fasc. 2 and 3.

Rava describes the case of a young man of twenty, with complete paralysis of the six muscles of the eye and the levator palpebræ; the sphincter iridis alone was not affected. The power of accommodation could not be tested. The eye was slightly turned downward and inward, and could not be moved from this position. Although the disease had been preceded by a long-con-

tinued attack of intermittent fever, combined with severe headache, the author had to exclude a cerebral case on account of the intact movement of the iris, and designate the paralysis as simple rheumatic. Complete recovery after six weeks of electric treatment.

Affezione Dolorosa del Nervo Sopraorbitale. Neurotonia, Guarigione, Quadri Statistiche Frammenti d'Oftalmologia, Roma, 1882.

Angelucci performed *neurotomy of the supra-orbital nerve* with good result in a case of *intermittent neuralgia*, which had lasted two years. The accompanying *megrim*, as also the spasm of accommodation and of the orbicularis muscle, disappeared very soon after the operation.

A Case of Intermittent Neuralgia, with Retinal Irritation. Medizins-koje Obosamije, July, 1882, p. 71, Flatow reports a case of intermittent quotidian neuralgia between the brows and in the lid, accompanied by extreme photophobia, cured by quinine.

L'Elongation des Nerfs et de ses Applications au Traitement de la Neuralgie du Trijumeau. Gaz. d' Ophth., No. 5, 1882.

Badal stretched the supra- and infra-orbital nerves in the cases of two women with neuralgia of the fifth nerve, paralysis of the oculo-motor, and atrophy of the optic nerve. The success was very moderate.

Contribution à l'étude de l'Élongation des Nerfs Craniens. Arch. d' Ophth., vol. ii., No. 4.

Alexandroff stretched the supra-orbital nerve in a very nervous man of thirty-one, who suffered from severe blepharospasm on both sides, *tic douloureux*, and *hyperæsthesia of the skin of the face*. On the right side of the brow there were old scars. On the right side complete success was obtained; on the left, marked improvement.

Clinical Contributions to the Knowledge of Orbital Tumors. Inaug. Diss., Zurich, 1882.

Huber publishes two cases of bony exostosis of syphiloma of the roof of the orbit, one of adenoma in the orbit, one of a round-celled sarcoma beginning in the right lachrymal gland, one of a spindle-cell sarcoma of the same origin, and one of a congenital dermoid cyst of the orbit. The majority of these cases were operated upon. They proved that tumors which generally are considered very dangerous may be removed with the best results, and that enucleation, besides, is necessary in only the worst cases. One eye, which had undergone considerable changes, recovered its normal condition and functions to an unexpected degree. The results of the operation seem to indicate that a number of anomalies of structure and function

of the globe are due to simple mechanical influences.

Osteoma of the Orbit The Lancet, No. 22.

Hulke, in a girl of four, removed an osteoma springing from the floor of the orbit.

On a Case of Ivory Exostosis of the Orbit. Ophth. Hosp. Rep., vol. x., p. 303.

Twedy, in a man of twenty-five, found an ivory exostosis, which occupied the upper and inner part of the orbit, and had its origin in the region of the lachrymal sac. The autopsy showed that the tumor extended into the frontal sinus. The latter was so distended by it that the anterior lobe of the cerebrum had been displaced. The tumor also penetrated into the nasal cavity and into the sphenoid bone; here it had caused a basilar meningitis.

Enchondroma of Orbit. Brit. Med. Jour., April, 1882, p. 615.

Reid, in a young man of nineteen, removed a tumor of the outer wall of the orbit. It adhered to the periosteum and extended back as far as the optic foramen, and completely enclosed the lachrymal gland. Five months later the tumor had again formed, and was again removed. Microscopic examination showed it to be an enchondroma.

Cisti Orbitaria. Ussernazione Clinica. Gazz. d' Ospidali, Nos. 31 and 32. April, 1882.

Saltini. In a man of forty-seven observed a cyst in the right orbit. The globe projected 1 cm., was turned downward, and immovable. The fundus showed the usual symptoms of stasis. The cyst was cured by drainage. It contained crystals of cholesterine and hematoidine, and blood pigment and fat corpuscles. Saltini considered the cyst to be an acquired one, to be of serious kind, and to have perhaps sprung from the mucous sac lying between the tendon of the superior rectus and levator palpebræ.

Kystes Dermoides Periorbitaires. Observation d'un Kyste de la tête du sourcil. Gaz. d' Ophth., No. 8, 1882.

Carré. In a man of twenty extirpated a dermoid cyst the size of a pigeon's egg from the upper part of the orbit. The tumor, though scarcely visible, had been observed at the age of one and a half years.

Serous Cystic Tumor in Eyebrow. Trans. Oph. Soc. of the Unit. Kingd., vol. ii. p. 251, 1882.

Nettleship saw a large oval cyst at the orbital margin near the eyebrows. When punctured a thin yellowish liquid escaped, which soon formed again. By injecting tincture of iodine the tumor was reduced one-half.

(To be continued.)

CORRESPONDENCE.

Sewer Gas—The Germ Theory—Obstruction of the Bowels.

EDS. MED. AND SURG. REPORTER:—

There is a great deal written about the pernicious effects on one's health of sewer gas, impure air, defective ventilation, etc., etc., but what makes me skeptical about this matter is this; I know an old man—over 65 years of age—who enjoys most excellent health, very seldom having occasion to consult his physician, and yet this old man never cleans his teeth. The remnants of hearty meals, eaten perhaps months ago, are visible on his upper and lower incisors, and the odor of his breath is simply horrible; all the foul odors that one has ever had any experience of in the dissecting room and in performing post mortems are as attar of roses in comparison. This old man has been inhaling the foul exhalations from this decaying vegetable and animal matter, not excepting an intermixture of limberger cheese for years, and yet there is no visible impairment of his health. Is it any wonder that I am skeptical in regard to many of these fine-spun theories? Then again in regard to the theory that consumption is caused by a certain microscopical organism, the terrible bacillus. Well! I confess I have given some credence to the germ theory of disease, but this is too much. I cannot receive it just yet awhile. Perhaps when it is proven that tuberculosis is not hereditary, or that it is hereditary but that those ubiquitous bacilli have made their homes in the spermatozoon of the male or ovum of the female before impregnation takes place, and have in this way made their calling and election sure to this new mansion house, the body of the consumptive. I say, perhaps, when this germ-theory in regard to consumption has been reconciled with the theory of its being an hereditary disease, or the latter theory is abandoned as untenable, I may accept and believe in the new theory that consumption is a zymotic disease; but at present I am skeptical in regard to the existence of this bacillus as a cause of consumption.

Some time ago I had a case of obstruction of the bowels, accompanied with persistent hiccough. After trying a large number of remedies to control the hiccough, I think I finally succeeded by putting on a very tight bandage, covering the abdomen from the pubes to the mammae. Of course, I gave morphine, to relieve pain, in large doses, but it alone appeared to have little effect on the singultus, while the bandage stopped it instantly. My idea was, that steady pressure upward on the diaphragm would stop its tendency to spasmodic contraction, and so I think it did. The case recovered.

H. NYE, M. D.

Enon Valley, Pa., January 11, 1884.

NEWS AND MISCELLANY.

An Outrage that Appeals to Human Nature Everywhere.

The Lancet, December 29, 1883, says: "The treatment of the Nihilists in the fortress of Peter Paul at St. Petersburg, calls for a protest in the name

of humanity. If a culprit deserve death and the law of the country sanction capital punishment, then let the extreme penalty be inflicted, but with the utmost decency and promptitude possible. Should the authorities, however, think fit to commute such sentences or to sanction lesser penalties, such pretended mercy should be something better than a mere pretext to shield from public opprobrium the gradual torturing to death of helpless prisoners. Certainly medical men should have no share in such inhuman practices. The letter written in blood received from one of the noisome cells situated below water-mark in the prison of Peter Paul, and summarized by the *Times* of last Friday, has also been communicated to me, and I would call attention to some details not yet published in England. The food, which should be the same as that given to common criminals—but the amount is not specified in the regulations that apply to the political prisoners—is never enough. No tea is allowed; a little plain hot water is served for the prisoners to drink both morning and evening. But, either through defects in the water pipes, or from other causes, this water is always dirty, and sometimes fetid. There is a large proportion of sand in the prison bread, the gruel is generally mouldy, and on Wednesdays and Fridays, instead of cabbage-soup for dinner, they have pea-soup flavored with the coarsest oil. On Sundays a few shreds of meat are occasionally discerned in the soup. The diet and foul atmosphere soon produce diarrhœa and dysentery, followed by anæmia and scurvy. The elder physician, who has passed his eightieth year, never ventures into a cell; while his junior is so careful not to lay himself open to the suspicion of sympathizing with the prisoners, that he visits them surrounded by gendarmes and goalers, and does not dare to feel their pulses. He has, however, had the courage to reply to their complaints: 'Against your ailments we have no remedies'—an answer which, now that it has been made public, will probably cost him his post, if not his liberty. A lady suckling her child, Madame Jakmova, is stated to be left in an underground cell, to fight night and day with the rats that seek to devour her infant. Till the government has sufficient humanity to allow the medical officers to alter the diet and general regimen of their patients, it is mere hypocrisy to call in their services. The medical profession should resent this insult to their science. Their mission is to help to heal the sick, and not to aid a government anxious to rid itself of obnoxious political adversaries."

Post-graduate Schools.

The post-graduate schools, both in Philadelphia and New York, have been well attended this winter. At the "Philadelphia Polyclinic and College for Graduates," there have been 72 paying pupils in attendance, and between March 1st and December 31st last, there were over 3800 new patients in attendance.

The New York Post-graduate Medical School has been so successful that it has secured much larger quarters, which it will occupy in February. The total number of its students has been 140, and its clinical material very abundant.

It is gratifying to learn that the profession at large are availing themselves of the advantages of these special courses.

The Northwestern Medical College.

We publish with pleasure the following special dispatch to the *St. Joseph Daily Herald*:

JEFFERSON CITY, Mo., January 8.—The State Board of Health of Missouri, in session here to-day, fully exonerates the Northwestern Medical College, of St. Joseph, from all charges against it, and recognizes it as standing on a level with the best schools of the State. There was a full meeting of the Board, assisted by Drs. Rouch and Talifara, of the Illinois Board.

The Board were satisfied that the charges made against the college were unfounded, and the result of animosity.

International Congress of Hygiene.

The Secretary of State informs the *Med. Record* that "according to a note from the Minister of the Netherlands here, the International Congress of Hygiene will hold its next session at the Hague, on August 21st next, and that governments, states, corporations, etc., are invited to send delegates."

Ohio State Sanitary Association.

The first meeting of this association will be held at Columbus, Ohio, February 14 and 15. The address of welcome will be by Dr. J. F. Baldwin. Papers will be read by Drs. W. M. Beach, C. M. Finch, Prof. E. H. Hyatt, Dr. John McCurdy, James E. Reeves, and a number of others.

Measles in Baltimore.

For the last month quite a severe epidemic of measles has been prevalent in Baltimore, Md. At one time nearly 500 cases were reported. It began about December 1, and the mortality has been as high as about 20 per week.

Items.

—California's vineyards are rivaling her mines as a source of profit.

—There are about 2,400 female physicians in the United States.

—The British Ophthalmological Society has decided to found a museum and a library.

—The next session of the American Public Health Association will be held in St. Louis.

—Dr. A. F. Holt, of Cambridge, has been appointed Surgeon-General of Massachusetts.

—A new society, called the Gynecological and Obstetrical Society, has been organized in Paris.

—Dr. Gustave Rivet, *interne* of Charité, died recently of diphtheria contracted during his service in the hospital.

—A Government Quarantine Station for imported cattle has been permanently established at Garfield, N. J.

—Dr. Leonard Weber reports two fatal cases of diabetes insipidus in children in the *Amer. Jour. Obst.*, January, 1884.

—A bill to regulate the practice of medicine and surgery was recently introduced in the General Assembly of Virginia.

—Dr. W. W. Watkins has been appointed Lecturer on State Medicine and Hygiene, in the St. Louis College of Physicians and Surgeons.

—In the *Lancet*, December 29, 1883, Mr. O. C. Mawne reports a case in which colotomy was performed five weeks after ovariectomy, with recovery.

—Dr. W. A. Duncan showed the Obstetrical Society of London a large fibro-cellular tumor, involving the clitoris and both nymphæ, which he had removed.

—A so-called epidemic of chorea is said to have broken out in a girls' school at Moscow, and to have manifested itself simultaneously in eighteen different houses in which the school-girls reside.

—The statue of Liebig, at Munich, has been mutilated by the pouring over the entire left side of the figure of some dark colored liquid, which has corroded the marble. The perpetrators of the outrage have not been discovered.

—A man who abstains from liquor, as shown by insurance tables, at 20 years has a chance of living 44.2 years; at 30, 36.5 years; at 40, 28.8 years. An intemperate man's chance at 20 is 15.6 years; at 30, 13.8; at 40, 11.6.

—The New York Coroners' Statistics for the year 1883 are as follows: Sudden deaths from natural causes, 1,296; deaths without medical attendance (chiefly of infants), 1,231; deaths from accidental injuries, 414; suicides, 160.

—A physician of Syracuse has been found guilty of grave-robbing. The body stolen was that of a prominent resident of Camillus, a village near Syracuse, who died in March last, and it was discovered at the medical college in the latter place.

—The Michigan Legislature has passed, by a nearly unanimous vote, a bill requiring school teachers to pass an examination in physiology and hygiene, with particular reference to the effects of stimulants and narcotics on the human system.

—Dr. Meadows reports a foetus successfully removed by abdominal section from a suppurating extra-uterine cyst. The pregnancy had occurred about fifteen months previously. The cyst was stitched to the abdominal wall, and its cavity washed out.

—A committee has been formed, representing the profession in various parts of the country, to obtain funds for the erection of a monument to the late Dr. Sims in New York. Dr. Fordyce Barker is the chairman, and Dr. George F. Shradley is secretary.

—In the *Boston Med. and Surg. Jour.*, Dec. 13, 1883, Dr. Bradford reports a case of calculus in a child ten years old, which had evidently existed since babyhood. There was no history of blood or pain. He occasionally pulled on his penis, and at times held his water for twenty-four hours.

—There are not less than 200 graduates of medicine, says the *Chicago Med. Jour.*, who cannot spell correctly the word "diploma." The following methods are on record in the office of the

Illinois State Board of Health: diplomer, diplomy, diploma, diplomy, diplomah, dipluma, dipluma.

—*Virchow's Archiv* for December contains a summary, by Dr. Uhde, of Braunschweig, of the examinations of pork for trichinæ in the Duchy of Brunswick. The total number of carcasses of swine examined was 120,766. Of these, eleven were found to contain trichinæ, and 109 were otherwise diseased.

—The English census reports show that the proportion of the blind to the population has not only decreased with each successive enumeration since 1851, in which year account of them was taken for the first time, but the decrease in the decade ending in 1881 was much greater than in either of the preceding intervals. The number of cases in 1881 was 22,832, which was one blind person in every 1,138.

—The Duparque prize will be awarded by the *Société de Médecine*, of Paris, in 1885, for the best essay on the pathology of the ovary, and especially oöphoritis. Competing essays, which must be written or printed in French, should be sent to M. le Dr. Thorens, 34 Rue de Penthievre, Paris, before the 1st of January, 1885, and they must not have been published more than two years before that time. As the prize was not awarded in 1883, it will amount to 1,200 francs, in addition to the gold medal.

QUERIES AND REPLIES.

EDS. MED. AND SURG. REP.:—

Dear Sir.—Having profited so much by the suggestion of the contributors of your valuable journal, in the prescribing of salicylic acid, I venture to ask you if you can be of assistance to me directly.

What combination has proved to be most successful in the condition known as menorrhagia? By placing this among your "Queries and Replies," you will greatly oblige,

Helena, Montana Territory.

W. B. W.

Jequirity in Granulated Lids.

EDS. MED. AND SURG. REP.

Please give particulars as to using jequirity in granulated lids, and oblige
AN EARNEST INQUIRER.

Ans.—Jequirity, the seeds of the *abrus precatorius*, was first employed scientifically by De Wecker, the famous Parisian ophthalmologist, who received the hint from a patient whom he had unsuccessfully treated, and who on his return to his home in Brazil subjected himself to the popular treatment, as it is known among the natives of that country. De Wecker, acting on the instructions furnished him, prepared an infusion by bruising the seed to a fine powder, and then adding the proper quantity of water and allowing it to macerate for twenty-four hours. This infusion applied to the conjunctiva possesses the peculiar property of exciting a specific inflammation, which, in the majority of cases, is of a diphtheritic nature. After this jequiritic inflammation has subsided, it is found that the trachomatous bodies have disappeared.

Dr. H. R., of Ohio, asks about the use of iodoform in gonorrhœa. It is mentioned as a valuable remedy in Napheys' *Surgical Therapeutics*, p. 574, on the authority of an Italian physician. The only objection to its use is its odor, which after all, is not particularly bad. We have ourselves directed it in herpes preputialis, with satisfactory results.

BLOOD-LETTING IN THE YOUNG.

BY HIRAM CORSON, M. D.,
Of Conshohocken, Pa.

It was my good fortune to attend the lectures of Prof. Thomas Chalkley James, and to hear him say that in certain conditions of still-born children, we should draw blood from the cord to relieve the brain. In turning to his edition of Burns' Practice—then our text-book—I find on page 10 the following "In whatever mode children are still-born, the effect is referable, either to compression on the cord, first suspending and then destroying animation; or to pressure on the brain; or to a state of insensibility and feebleness, preventing the action of respiration from taking place." Then, again on page 11: "If, however, respiration do not begin, we are to open with a lancet or scissors one of the umbilical arteries, from which blood spouts in a small stream; and in a short time thereafter, breathing commences." This was the utterance of Prof. James in his advanced age after a life-long experience. I was fortunate, too, in hearing Prof. Dewees give the same advice to us—his pupils in the University of Pennsylvania—when adjunct to Prof. James; and now, in turning to his "Midwifery," published a few years later, I find the following on page 191: "The child, from being long-delayed in the passage, or from having its neck tightly begirt with the cord, may be still-born; in this case its face will be black, or livid and swollen; the arteries may have ceased to beat, or they may beat vigorously. In such cases,

nothing can save the child from immediate death but the instant abstraction of blood by cutting the cord. Should the pulsation have ceased, we may sometimes still succeed in drawing some blood by forcing it from the cord, and then employing inflations, etc. If pulsation continue we must also abstract blood by cutting the cord—the quantity to be drawn must be regulated very much by its effects. When respiration is established we need draw no more; but until some signs discover themselves of this being about to take place, we may abstract pretty freely, as this process most probably is interrupted by the congestive state of the brain, which can only be removed by pretty ample depletion." Dr. Dewees was a man very eminent in his department.

The eminent Prof. Hodge, who succeeded Prof. Dewees in the chair of Midwifery, seems to have believed in, and taught, the same practice; for I find in his Principles and Practice of Obstetrics, published in 1864, that he has given much attention to the condition of children born either in a state of complete or of partial asphyxia, and of the treatment of such cases he says, on page 214: "The treatment in both forms of asphyxia is precisely the same with one exception: in the congestive form where some activity remains in the circulation, and where the brain and heart are oppressed with a quantity of venous blood, experience proves that it will be advantageous to allow the vessels of the cord to bleed to the extent of half an ounce or more, after birth—for this purpose the cord may be divided without the application of the ligature."

Commencing practice influenced by such teaching, it has never occurred to me, during fifty

years of labor in the sick-room, to regard any age as prohibiting remedies useful in any other. The young child with an oppressed, congested brain, I attacked with the same means of cure that I had seen efficient in persons of mature age laboring under similar sufferings. I could not believe that the weak, puny child, comatose from congestion of the brain, or shrieking from inflammation of its membranes, should be left without the remedy which I had seen bring so great relief in older persons; and I have therefore, in years gone by, bled children in such affections with the most gratifying results—so in all affections where bleeding was useful in grown persons, I never hesitated to use it in children, however young. In croup cases, I have bled scores and scores of times with instant and marked relief; not *always* with permanent success, but oftentimes with immediate and ultimate relief. Let me describe a single case. Called at midnight, more than forty years ago, to see an adopted child, about one year old, a small, dwarfish child, of an unfortunate unmarried girl, I found it lying across its foster-mother's lap, the neck stretched out, and breathing like a child in the last stages of suffocation. As I approached it, the mother said: "Doctor, you have come too late; it is dying." And so it seemed indeed; but as it held on a few minutes, while I watched its labored struggles for breath, I proposed to bleed it; to which she offered no objections. It lay in a favorable position for bleeding from the jugular vein, and in less time than I have been talking about it, the blood was spouting into the bowl in the rapid way in which it comes from that vein. It soon fainted so dead that the mother said: "Doctor, you have killed it." I replied, "It does seem to be dead," but knowing how important a little shaking, and rolling, and lowering the head is in such cases, I lost no time in effecting these necessary movements, and directly there came a gasp, then another and another, and in a few moments it was as free from difficulty of breathing as if it had never had any. She still lives in the neighborhood, and has a large family of healthy boys and girls.

Some readers will say, *that* must have been spasmodic croup. Perhaps so; and yet I doubt whether a single one of those objectors can tell a case of spasmodic croup from membranous till after the post-mortem examination has testified. I have bled many quite young children from the arm, the foot, the jugular vein, in croup, and not once that I have regretted it. In scarlet fever I have bled them with great relief; quickly reduc-

ing the temperature and relieving the brain when convulsions were threatened or actually present.

Were it not that I now have always at hand a powerful and efficient means to accomplish the same purpose—namely, the pouring of cold water on the head from a height of two or three feet, and sponging the whole body with cold water—I should resort to the lancet in like cases as being infinitely preferable to the nauseating, depressing effects of *veratrum viride*, or the danger of poisoning from *aconite*.

I might say more on this subject, but I have, doubtless, already shocked the feelings of many excellent physicians who are filled with fear of the lancet, and with belief in the antagonisms of medicine, and the antipyretic powers of drachm doses of quinine, who see approaching septicæmia and heart-clot in every disease, and who are blanched with fear that in the battle daily waged by millions of bacteria on the one side and by the brave Lister and his hosts on the other, victory may perch on the banners of the former. We ought not to expect minds thus occupied to look back on the history of medical science; for of what value can the experience of men of twenty or forty years ago, who knew not the wonderful discoveries of the last decade, be to them, who have listened to recent teaching?

Many persons who are in favor of bleeding are afraid to bleed from the jugular vein. It was fortunate for me that I did not know of the danger which is now spoken of, as coming from the introduction of a bubble of air passing down the vein, when the pressure is removed in order to stop the bleeding, or from wounding a nerve. When the finger (you need no ligature) is pressed on the jugular vein, the vein above the finger becomes very prominent instantly; you open it with the lancet, and it bleeds rapidly; then, if the finger be suddenly taken from the vein, while the blood is running in the bowl, it is said that air may slip into the vein (which, below the finger, is supposed to be empty down to the sub-clavian vein), and pass directly to the heart, causing, it is said, instant death. Why a bubble of air carried to the heart should cause death, I do not know—indeed, I don't believe that it can—but I confess that I knew nothing of such a danger, and took no precautions against it, and no accident happened in any of my cases; but in doing it now, I would stop the blood by putting the finger of one hand over the orifice before I would take the other away from the vein, thus avoiding the *supposed* danger. I never happened to strike the small nerve which crosses the vein

or lies alongside of it; or if I did, it gave no sign of injury. I might crowd pages with cases of children bled in various affections. Within a year I have bled two children, under nine years, freely, to relieve them from pneumonia, and with prompt relief.

Thirty-two years ago I bled a child of only two years who had been poisoned by eating the green stalks of Jamestown weed (*stramonium*) four hours previous to my seeing him. I quote from my note-book: "The pulse was so frequent that I could not count it at all; the eyes wide open, and the child wholly blind—it felt about for things; nothing that was held before the eyes was noticed; even a lighted candle held before and close to the eyes was evidently not seen; the face was very red. Treatment: *Ipecac* freely, until free vomiting was produced and large quantities of the leaves and stalks of the plant thrown from the stomach; bled him freely and applied cold water to the head. The hands and feet being cold, mustard plasters were applied to the latter. In two hours there was an evident amendment—the child was quieter (there had been convulsive jerkings of the feet and arms, as though fits were coming); the pulse came down, was more regular, and could be counted. I had then been there three hours, and it was midnight—directed cold to be kept to the head, and left it. It fell asleep at 2 a. m., did not awake until 6, and then could see well and seemed quite rational. At 8 a. m. I found it quite well." I hear Mr. Objector say—"Well, what of it? What good did the bleeding do?" and I answer: "What harm did it produce?"—for your objection to it is, not alone that it is useless, but that it does great harm. Suppose that in a like case a physician of to-day had not bled it, but, impelled by the present fashion, had given antagonistic remedies, and in two or three days the child had improved as greatly, in spite of them, as it did in a few hours under the bleeding, would we not have had the case heralded as one showing the great value of the remedy which had, according to the most scientific teaching, been sent after the *stramonium*? Was bleeding a rational remedy? Yes. The present doctrine that poisons are absorbed, and act by being carried to the brain by the blood—to which I do not wholly subscribe—is pretty generally believed. Now, if that be so, the removal of a portion of this poison must be useful by lessening its amount, thus reducing it to an amount not fatal in some cases; but still more useful by protecting the brain from a fatal congestion. What were the symptoms? The face red,

the eyes wide open, the hands and feet cold, the pulse so frequent that it could not be counted, the child blind. Was there no congestion here? Was it not necessary to draw the poisoned blood away from the brain? What antagonistic remedy would have taken away the excess of blood that was pressing on the nerves of sight and hearing, making the child deaf and blind? I may sum up by saying that there is no child so young that bleeding may not be practiced for its relief, in all affections in which in adults it is admissible or useful.

I have thus truthfully presented a few cases to show that bleeding may be practiced with safety and advantage on children of any age, and on persons however aged; and in this opinion I but agree with many others who have had long experience in practice. The question arises now: How is it then that physicians who were used to see so good results from blood-letting gradually abandoned it, until now it is considered almost a useless and dangerous remedy, and instead of being taught in medical schools, is denounced in coarse and unmeasured terms as something to be dreaded? I have lived through the years in which this change was wrought, and the cause of it is to me no mystery. About fifty years ago the Thompsonians appeared with their hot and cold baths, their *lobelia* and No. 6, which made prompt and decided effects, and oft-times good results, and their rallying-cry was against blood-letting; "that the blood is the life; that no one has any blood to spare." We beg the objectors of to-day, and especially those who have graduated within a few years and are so loud and denunciatory of blood-letting, not to believe that their teachers, who are now claiming it as growing out of their observations, and as resulting from their experience, had anything to do with originating the hostility to blood-letting. They are only followers.

Even a few years before Thompson assailed us, Hahnemann came with his new system; and though he was gentle, not denunciatory of us, yet he made converts to his opposition to our bold, harsh treatment, so aggressive, as he charged, to the human system.

Then about forty years ago came the Eclectics, and claiming to select the best remedies from all sources, pounced upon calomel and our blood-letting as measures unnatural and fraught with danger and death.

Thus assailed, the timid and craven yielded; some sought safety by deserting our ranks, and others profit by joining in the hue and cry against

blood-letting, while they professed to stand with us in other modes of treatment. Medical teachers, fearful that their enemies would entice or frighten the pupils from the "Old Schools," as our colleges were derisively called, yielded as the timid and craven practitioners had done, and began to teach that a change had taken place in the human system, which rendered the abstraction of blood less necessary; and as they dwelt on this topic, they gradually, from year to year, came to believe that in no case should a person be bled, until now they fancy that this enlightenment came from *their* greater knowledge of diseases and remedies. I am well convinced that there has been no change in the nature of our diseases, or in the human system, which precludes the employment of blood-letting, either in the old or the young, or prevents it from being as efficient as it was half a century ago: and I offer these few cases as proof of my opinion.

In the letter which Dr. Michener sent to me concerning blood-letting in the old, he dwelt upon its use in the very young. He says:

"In relation to blood-letting in early childhood, I have performed it as early as the fourth or sixth month.

"In cases of recurrent or periodical convulsions in early childhood, I have found it beneficial, and in several instances it appeared to effect a permanent cure.

"Of letting blood immediately after birth, I can speak with more confidence; it has been almost a specialty with me.

"We sometimes find the veins of the cord remain distended, after the artery has ceased to pulsate; along with this, I have observed that the mucous membrane of the lips and vulva, etc., present a darker color; and what is more important, the child is slow in coming to its breathing, the inspirations being accompanied by a spasmodic effort and evidence of pain. There is hardly any case in which I have found blood-letting more relevant; an ounce of blood allowed to escape from the distended veins will generally afford immediate relief.

"The inquiry has hardly been sufficiently made how far this treatment would assist in the restoration of still-born children."

Strong testimony this. Wonderfully strong, if it had been uttered by even the weakest of professors; but as the utterance of a mere practitioner, it will be subject for laughter to students.

—A Japanese student has been appointed assistant to the Professor of Anatomy at Berlin.

MONSEL'S SOLUTION AS A TOPICAL APPLICATION IN DIPHTHERIA.

BY W. M. HEPBURN, M. D.,
Of Jeddo, Pa.

That I am taking up a subject fraught with many difficulties, I am only too well aware. I have but to look into a book written by one of America's brightest lights, to see the following emphatic statement: "As the local disease, in diphtheria, is only the visible manifestation of the constitutional infection, remedies applied only to the throat exercise very little, if any, control over the disease." Yet I turn to the writings of another honest and skilled practitioner, and find he informs us that "Diphtheria is first local, and afterward a general disease; that the poison of the disease finds a favorable nidus in the mucosa of the throat, and rapidly grows there; that the first symptoms of the disease are therefore wholly and exclusively local; and that it is only when the epithelial barrier is broken down that the blood and the whole body becomes infected." Confusing as such contradictions are, I nevertheless am convinced of the efficacy of certain drugs, used locally, in this disease. Whether we believe diphtheria to be at first a general or local disease, we may, I think, assert that the germs, be they vital or chemical, find their way into the system by direct implantation through the surrounding air, or by water and food. Could it be proven that the disease manifests itself first locally, then we should all eagerly receive any well-tested and approved local remedy. As it has not yet been satisfactorily shown that such is the case, we can alone by practical use of drugs, and in a series of well-tested cases, show their efficiency.

I remember reading an article entitled, "Topical Treatment of Diphtheria," in which the writer strongly advocated the use of the sub-sulphate of iron, applying it thoroughly to the throat and in an undiluted form. The article closed with the following words: "Nor do I recommend the persulphate of iron as a specific in diphtheria; I say for it only this: If I had to take my choice between it and all other kinds of treatment, general or local, I would select it in preference to all the rest."

This article, as is usual when any drug is vaunted as of much account in diphtheria, caused a great discussion, especially as to how it could be good when diphtheria is, from the first, a constitutional disease. Desiring to find out for myself the virtues of the medicine—the theoretical conclusions being, to my mind, entirely secondary—I determined, when the opportunity occurred,

to give it a thorough trial. Having since last spring been assisting a physician who has by far the greatest number of families under him of any gentleman in the state, and an epidemic of diphtheria occurring just at the time, I took my field. I not only used the Monsel myself, but requested one of my associates to also try it, which he promised to do. This fall another epidemic broke out. I did not, being very hard worked both times, keep a minute account of all my cases; but the results from the use of Monsel are most effectually impressed upon me—not only from my own experience with the drug, but also from what I know of the use of it in Dr. W.'s field, where I was called in consultation, and also from statements made to me by my associate.

I had altogether some twenty cases, varying from slight to very severe attacks. Dr. W. had forty-four cases, some of them slight, and might be called by some practitioners diphtheritic sore-throat. But, what is diphtheritic sore-throat? If an epidemic of scarlet fever should be raging in my field, be it mild or grave, have I not a right to call all cases of it scarlet fever? Slight or grave, is it not the same poison? And if I prove, by grave cases, that a certain remedy is efficacious in cutting short an attack, have I not a right to believe that many of these cases were light attacks owing to prompt treatment? Dr. Chambers, in his book entitled "Renewal of Life," strongly urges the prompt use of an emetic in the very incipency of typhoid fever, and has, apparently, convinced himself of his ability to cut it short by expelling and prohibiting further absorption of the poison. Nor is he the only eminent practitioner who believes in such results being attained.

Facts, after all, are what we want; and if renowned M. D.'s firmly believe they can cut short typhoid—a universally acknowledged constitutional disease from the beginning—does it seem ridiculous that in an affection in which the profession are at variance as to whether it is at first local—I say, does it seem ridiculous that an effort should be made to find a local remedy?

I before remarked that Dr. W. and I together had sixty-four cases. Of these, six died. Two of the deaths were in my field: the first, a child of six years, whom I was not called in to see until the fourth day of the attack, and the throat was then gangrenous. My second case, a boy twelve years old, was a very severe one. The throat was terribly swollen and covered by a diphtheritic membrane—the breath excessively fetid; yet by freely applying Monsel, I had the satisfaction of

seeing the patch disappear and the swelling subside; but unfortunately the disease attacked the larynx, and thus caused his death. Three of the four deaths in Dr. W.'s field, he tells me, were due to laryngeal complication; the fourth from hemorrhage. We made applications of Monsel undiluted, to all ages from eleven months to sixty-five years, and have yet to see any deleterious results from such heroic treatment.

But you naturally inquire, Don't you use any other medicines in conjunction with Monsel? Yes, I do. I use steam inhalations, chlorate of potash, tincture of the chloride of iron, quinine, and stimulants, if needed.

I suppose these acknowledgments may cause a smile to pass over my readers' countenances. Chlorate of potash, for instance, is vaunted by Dr. Seeligmuller, of Halle, Prussia, as a specific in diphtheria, even as much so as quinine in intermittent.

So again, we hear tinct. of iron and quinine exalted as the most efficient; but to add to my facts, let me state that I have allowed some of my patients—comparatively mild cases—to use only potash and iron. Their convalescence was *always* slow. On making an application of Monsel to an *equally* severe attack, I always look for marked improvement in 24 hours (my next visit). To illustrate: Dr. G.—another of my associates—had four equally bad cases in one section of his town. Two died. In these four, iron, potash, stimulants, etc., were used; Monsel was not. A fifth child was attacked; apparently, the disease had taken hold with as great violence as the others—aching bones, bounding pulse, temperature 103°, etc. He was called early, applied Monsel, and in 36 hours the child was running around the house, feeling good.

Do I believe Monsel to be a specific in diphtheria? By no means.

Sometimes any and all remedies seem utterly useless, but I would not be so cynical as to indorse the following statement, made by a well-known physician:

"Diphtheria depends upon a poison, whatever that may be, and the gravity of the disease is measured by the amount of the poison in the system—if this be of a certain quantity, the patient will die; if less, then he will recover."

The physician, like the commander of a ship, must face the storm and try to bring his precious cargo through.

Sometimes such a tornado bursts over him as to make him feel his utter helplessness, but *far* oftener he can face it with such courage and skill

as that all who stand by him have to acknowledge that his presence had much to do with the result.

How do I account for the happy effect of Monsel in this disease?

If we believe diphtheria to be local at first, and that the poison is gradually absorbed; then, that by powerfully constringing the vessels and thus preventing further absorption, Monsel accomplishes its task, might be a reasonable explanation.

If, however, diphtheria is to be constitutional from the first, I am at a loss to explain its virtues, and can but give you my knowledge of its practical effects, and leave it to you to use or discard.

A CASE OF "GALL STONES" OF TWELVE YEARS' STANDING.

BY J. E. HAINLINE, M. D.,
Of Cantril, Ia.

On December 10, 1882, I was called to see a gentleman who the messenger stated was suffering terrible pain, and could not possibly live long unless quickly relieved. I hastened to the residence indicated, and upon my arrival I found a man partially under the influence of chloroform, who seemed to be in great agony.

There was great anxiety in his expression. I advanced to the bedside, spoke to him, but he failed to recognize me. In answer to my question concerning the location of the pain, he clasped both hands to his right side and exclaimed: "It's no use to try to do anything, for I know I can't stand it long. I will soon be at rest." He continued in this strain for several minutes, occasionally calling for chloroform, which was poured upon a folded handkerchief he held in his hand, by his wife or some of the attendants, and which he immediately applied, covering his mouth and nostrils. This he continued until the pain was controlled.

Interrogating the wife, I was informed that on the 2d day of December he was taken with a similar attack; that he remained in bed five days, when the pain suddenly ceased, and having received a call to meet the county Board of Supervisors, of which he was a member, he started to the county seat. He remained away from home but two days, and returned, saying he felt badly. The same evening he was taken with a pain more violent than ever before, which gradually grew worse up to the time I was summoned. I found him very much jaundiced, the sclerotic was highly tinged by biliary matters, the liver enlarged, and the "gall bladder" greatly distended, as was also

the duct; bowels constipated, extremities cold, and heart's action weak.

Diagnosis was easy. There was spasm of the gall duct, produced by the attempted passage of biliary calculi. The condition of the patient at this time indicated that something must be done, and done quickly. I determined at once to withdraw the chloroform, and substitute therefor sulphate of morphia.

I was informed by the wife that he had tried morphia, and it did not seem to act well. She said the pain came on suddenly, and with such violence as to be unbearable; the chloroform acting rapidly, was used instead. I spoke of the dangers attendant upon the administration of chloroform, and also stated that the remedy exerted no curative effect.

I prepared the following:

R.	Morphiæ sulph.,	gr. ss.
	Aquæ puræ,	gtt. xlv.
Mx.		

Of the above I administered, hypodermically, fifteen drops. Within twenty minutes my patient seemed free from pain, and was resting quietly. I gave strict orders to have everything quiet in and about the room; to allow no one in the room except the nurse. Leaving half a grain of morphia, divided into two powders, to be taken during the night, should the patient become restless, I left, stating I would call in the morning.

I called the following morning, and found my patient vomiting and perspiring freely. He had thrown off considerable bile. I gave nothing to control the vomiting, deeming it an efficient means of cleansing the stomach, as well as relaxing the system.

In the evening I again called. The vomiting had continued irregularly during the day. I ordered small pieces of ice to be taken into the mouth, and permitted to melt before passing into the stomach; and in connection with this, I had also given a teaspoonful of fresh buttermilk every hour. In this manner I controlled the nausea.

On calling the following morning I was informed my patient had rested well, and that during the night he had had two copious stools, which I examined, and found to contain several small calculi, together with quite a large amount of bile, showing that the gall bladder had been pretty thoroughly evacuated. He was free from pain, the only discomfort being prostration and considerable soreness in the region of the liver and over the stomach. He was also very nervous.

I continued the same orders previously given, adding beef-tea to the diet. When I returned in

the evening, my patient was complaining of a slight pain again in the liver. I administered, hypodermically, fifteen drops of the morphia solution I had previously prepared, and left.

The following morning the patient was much improved, entirely free from pain, and very anxious to know what I thought of his case. Said he had been treated by several able physicians, but had derived very little benefit therefrom. I informed him that I must know more about his case before venturing an opinion as to a cure.

I obtained the following history of the case: L. W. C., æt. 56 years. Married; merchant. "Twelve years ago, while attending a public sale, was attacked with a severe pain in region of liver. Pain lasted two hours or more, when it suddenly left, and I felt no more of it for a month or two, when it returned. For past six or seven years it has occurred regularly every three or five weeks. Have used chloroform to control the pain, which has gradually, for the past year or two, grown worse. Am compelled to keep my bed for a week at a time. When pain leaves me I can go about my business, but feel weak and nervous for a few days. Scrofulous disposition; inveterate eater and smoker; not addicted to strong drink; have exposed myself; morbid appetite; in the habit of lunching freely just before retiring at night; in store have been in the habit of eating crackers, cheese, dried beef, raisins, etc." Friends told me he had often eaten nearly a pound of dried beef; very nervous and excitable; drinks two or three cups of coffee at every meal; bowels constipated, very much so for several days before attack; tongue heavily furred nearly all the time; liver enlarged; gall bladder also enlarged; slight palpitation of the heart after eating; occasional vertigo.

After a thorough examination, I informed the gentleman his case was curable; but that the cure was largely based upon his own actions. I said to him if he would only obey my restrictions I could promise him a cure. He promised to obey, but stated he had "no faith in the cure." With this understanding, I began the task.

The first step being to restore the digestive system to its normal condition, I gave the following directions: *Eat slowly, chew your food thoroughly, and drink nothing during meals, except in the morning after breakfast, take a single cup of coffee.* Avoid the use of pork; use beef, chicken, or wild game; use very little fatty substances; use no fried food; do not drink cold water for at least an hour before meals; use light bread and not soda biscuit; bathe in tepid soft water twice a week; smoke after eat-

ing, one cigar, and no more. To aid digestion, I prescribed the following:

R. No. 1.

R.	Pepsin,	3 iij.
	Ingluvin,	3 iss.
	Bismuth subnit.,	3 j.

M.—Divide into 27 powders.

Sig.—One powder ten minutes before each meal in one tablespoonful of sweet milk.

To keep up a good action of the liver, prevent stagnation of the bile, and the formation of calculi, I ordered:

R. No. 2.

R.	Podophylli peltati,	
	Leptandrin Virgii.,	āā gr. x.
	Sanguinaria canadensis,	gr. v.

M.—Divide into ten powders.

Sig.—One every night and morning.

The above was continued for four or five days, after which only one of the powders was to be taken at bedtime.

For the purpose of preventing a return of the regular attack, and dissolving any calculi which might form in the gall bladder, as well as relieving the irritation of the mucous membrane lining the duct, I prescribed the following:

R. No. 3.

R.	Ol. olivæ,	f 5 iss.
	Ol. terebinthinae,	f 3 ij.
	Ether sulph.,	f 3 iss.
	Ex. glycyrrhizæ fld.,	f 5 ss.

M.

Sig.—One-fourth teaspoonful four times a day for six days, then increase to half teaspoonful, and take three times a day. "Shake well."

The treatment above described was continued for six weeks, with the exception of "Prescription No. 2," which at times seemed to exert too great an influence on the bowels, and had to be suspended for a few days.

As there had not recurred the regular attack, and the patient had declared that he felt no symptom of its return, I made the following changes: For R. No. 1, I substituted the following prescription—

R. No. 4.

R.	Pepsin,	3 iv.
	Acid hydrochloric,	f 3 ss.
	Glycerinæ,	f 3 ij.
	Aq. destill.,	f 5 iv.
	q. s.	

M.

Sig.—Teaspoonful after eating.

Patient adhering closely to all directions. Condition greatly improved. Appetite becoming more natural. Liver considerably decreased in size. Eyes had become bright, skin clear, bowels regular, stools exhibiting a free flow of bile.

Gave one powder of R. No. 2 every three or

four days, and continued to give them whenever there was the slightest engorgement of the liver.

At the end of the third month withdrew all treatment except an occasional "liver powder," to which I frequently added during the fourth month a grain of proto-iodide of mercury.

Four months elapsed, and still no evidence of a recurrence of the difficulty could be discovered; digestive system performing its work satisfactorily.

During the fifth month, I ordered R. No. 4, to be taken morning and noon; and R. No. 3 at night in half teaspoonful doses. When there was a tendency to constipation, I ordered three of the "liver powders" (R. No. 2) to be taken in the afternoon, commencing at one o'clock, continuing every three hours until the three are taken. These powders were to be taken only when there was a tendency to constipation.

Sixth month. Withdrew all treatment, and my patient discharged. Up to this date (January 12, 1883,) there has been no return of the difficulty, and he has never lost a day from his business from the time he began treatment, except the first two weeks. Says he feels as well as he ever did.

One of the important features in the treatment of this case is his strict attention to the *physical laws*.

PRACTICAL APPLICATION OF MEASURES OF EXTREME CLEANLINESS IN ABDOMINAL SURGERY.

BY R. STANSBURY SUTTON, A. M., M. D.,
Of Pittsburgh, Pa.,

Fellow of the American Academy of Medicine, Fellow of
the American Gynecological Association, Associate
Fellow of the Philadelphia Obstetrical
Society, etc., etc.

Two years ago every surgical clinic on the continent of Europe, every operator of note in Great Britain, excepting *two*, and a great many American operators, were using carbolic acid either in spray or irrigation in surgery. The abdominal surgeons extended their use of the acid to instruments, sponges, wash-water, the surface to be operated upon, and to themselves. In fact, Listerism, pure or modified, was in use everywhere above mentioned, with a solitary exception. The exception was Mr. Lawson Tait, of Birmingham, England. Well I remember, at the session of the British Medical Association, meeting in Worcester in 1881, with what sly winks and significant looks of disapprobation his remarks on Listerism were received; and well I remember the speech I made in his defense upon that occasion. I had just finished a three months' visit to Dr. Thomas

Keith, and had become skeptical in regard to the wholesale carbolic acid system of treating wounds. At the late meeting of the American Gynecological Society, and also of the American Academy of Medicine, I advocated less carbolic acid and greater details of independent cleanliness.

The measures of cleanliness advocated in papers before these bodies, I have adhered to, using no spray or irrigation of carbolic acid since my return to the country in last February.

In this time I have done a large number of serious operations. Of these, the abdomen was opened in eight cases.

One of these cases was full of malignant disease, extending to the intestines and other organs, and after a bloody operation, in the presence of peritonitis, was lost from shock on the day of operation; fifteen pounds of sarcoma were removed, besides four gallons of ascitic fluid. The patient was a young woman, and the malignancy of the solid tumor in a belly full of fluid was not considered certain. Some twenty inches of intestines were separated from the tumor at the operation, and the pedicle of the right ovary was so soft that the ligature cut through it, and necessitated subsequent careful ligation in the ligamentum latum.

A second case, a multilocular ovarian cyst, seven years old, often tapped, and the subject of severe peritonitis, and then demanding another tapping or operation, was operated upon. About thirty-six square inches of adhesions were separated, and after considerable time all bleeding points were secured and the belly left clean and closed. She developed a furious peritonitis, and died in a few days. I was puzzled beyond measure in this case, as the most extreme care had been exercised. A few weeks later, however, I hit upon the probable cause, which was defective drainage and sewer-gas in the building. The operation was done in one of the best houses in the city, and the preparations and the details at the operation were simply perfect.

A third case was done in a private residence. The preparations were perfect, and the details of the operation were carefully carried out. I removed the left ovary and nearly four inches of the small intestine, diseased and adherent. The ends of the gut were carefully united with scalded silk sutures; a drainage-tube was left in the lower angle of the wound. This patient recovered promptly, and is still living and going about; it is now more than eight months since the operation.

A fourth case was done in the country. It was a double ovariectomy, both cysts large and multi-

locular. The patient was reported in good condition for several days later, then was seized with some complication about the abdominal wound, and was finally lost. I did not see her after the operation.

A fifth case was done in her own home in the city, a very poor hovel. The only thing to do was to operate or let the patient die. She was 65 years old; perfectly immense. The measures of cleanliness were badly carried out, from the conditions surrounding her. She did well for three days, and I had about concluded that she was safe. On the fourth day (July 4) a cannon was fired off near by. She raised up in bed, and accused the nurse of striking her on the head with something. She remained deranged, and died at the end of a week, apparently from exhaustion. Her wound was healed, and her symptoms had been anything but bad, aside from her mental distress. No iodoform had been used at the operation.

With the loss of all these cases, two in their own homes and two in a good residence, but with defective sewerage, I resolved to change my plans or stop operating.

In September I purchased a small dwelling house, on high ground, on the corner of two streets, with plenty of ground about it, and with unquestionably good sewerage, and opened it as my private hospital on the first of October, and all of my abdominal operations are now done there. The house is intended for only six patients at a time, and all its arrangements are made with a view to the welfare of the patients. In this house three ovariectomies have been done since October first. Every measure of cleanliness advocated in the papers referred to has been carried out, and the result has been success in every case.

In the first case a thermometer was never put in the woman's mouth, and her pulse did not reach 100 per minute. Wound healed by first intention. In the second case, the highest temperature was 100.2° F. In the third case, the highest temperature was 99 $\frac{1}{2}$ ° F.

The pedicle in all these cases, with the exception of the last, was tied with silk and dropped in. In the last case it was tied and burnt off with Keith's clamp and caustery iron, and the greater part of the omentum was treated in the same manner.

Not a drop of pus has appeared in the wounds, no fever worth mentioning has occurred, and recovery has been uninterrupted.

Now that the conditions believed to be necessary for extended success have been acquired, I pro-

pose to test them thoroughly, and to give the profession the benefit of them. I take pleasure in publicly thanking Mr. Henry Phipps, jr., of this city, for his Christian charity in paying the expenses of two of the last cases, both poor, but mothers of families of children dependent upon them to a great extent.

The same gentleman has placed in my hands a sum of money sufficient to pay the expenses of twenty more women who must have ovariectomy or hysterectomy done. The profession are invited to send any poor women requiring the operation. They will receive the same care as those who pay for themselves.

HOSPITAL REPORTS.

CONSERVATIVE TREATMENT OF TWO CASES OF CONGENITAL PHIMOSIS, WITH CUT OF INSTRUMENT USED.

CLINICS, OF WILLIAM S. STEWART, A. M., M. D.,

Professor of Obstetrics and Gynecology in the Medical-Chirurgical College of Philadelphia.

Reported by JOHN S. STEWART.

December 13, 1883.

GENTLEMEN: I have to-day a case which will be interesting to you, as I propose presenting a novel and original method of treatment which I have adopted in my private practice for some time.

Mrs. S— brings her child, aged eight weeks, suffering from what is called congenital phimosis; in other words, an abnormal condition of the penis. Attempting to retract the prepuce over the glans penis, we find ourselves unable to accomplish it, owing to an adhesion and contraction of the mucous or lining membrane, although the integument is not abnormally affected.

On examining this boy, we find the penis, scrotum, and surrounding parts, inflamed in consequence of his inability to micturate freely.

I hold in my hand an instrument which, although devised for another purpose, I have used in my private practice for several years for correcting these congenital accidents. This instrument, as you perceive, has three blades, and by introducing it into the narrow opening of the prepuce and expanding the blades we can very readily stretch the contracted mucous membrane suffi-

ciently to permit us to retract the prepuce until we can pass it behind the glans. Since adopting this method, I have not had occasion to perform circumcision, although in some instances the children had been suffering two or more years. Now, we will first place the child upon the table, on his back, and as this will not be a very painful operation, we will not administer any anæsthetic. I will now extend the prepuce in the line of the penis, asking an assistant to catch lightly one edge while I hold the opposite edge in my left hand, thus separating the parts; with my right hand I press the instrument gently within the orifice of the prepuce until I touch the glans, being careful that the point of the instrument does not enter the meatus.

I will now gently expand the blades; having completed the expansion, will withdraw the instrument and examine what has been accomplished.

We have succeeded in relaxing the redundant mucous membrane, but on withdrawing the prepuce back over the glans, I find persistent adhesion existing between them. This we will carefully correct by using a blunt instrument, as for example, a simple probe; and you observe as I near the corona I find deposits of caseous matter which have been secreted, and will be a source of irritation. This must be carefully removed and an application made of ung. petrolei to the parts—this being all that is necessary.

You see, gentlemen, we have had a bloodless operation, and one attended with little pain, compared with the old method of circumcision for such conditions. I will instruct the parent to retract the prepuce once daily, and to anoint the parts with cosmoline until our next clinic, when I will request to have him brought back, that you may be satisfied with the results of this method of treatment.

December 20, 1883—Gentlemen: Before bringing in any new cases to-day, I wish to present to you our little boy on whom we performed the conservative treatment of expansion of the mucous membrane for congenital phimosis. Both of the parents have come with the child to-day, because of their gratitude for the relief given him, the evidence of which we have before us.

[Here the Professor retracted the prepuce without any difficulty, the parts all being in healthy condition, and no irritation of surrounding integument as when first seen.]

January 3, 1884—Gentlemen: Mrs. B., a private patient from the country, yielding to my request, has brought her child, aged sixteen months, before us to-day—it having an affection similar to the one we treated a short time ago by my new method, which you recollect.

In this case of congenital phimosis there is almost entire closure of the orifice of the prepuce, and we are obliged to introduce a series of instruments, commencing with the small probe, until we are enabled to expand the opening sufficiently to admit this instrument, which we will christen "The Preputial Dilator."

[Here the Professor introduced the dilator and readily expanded the prepuce, and after withdrawing as before, dissected back over the glans, removing considerable caseous matter which had deposited around the corona; resulting as previously in a bloodless operation.]

REMOVAL OF RIGHT BREAST BY THERMO-CAUTERY AND FERRUM CÂNDENS.

CLINIC OF PROF. V. NUSSBAUM, MUNICH, BAVARIA.

Reported by Dr. J. H. VOJE, specially for the MEDICAL AND SURGICAL REPORTER.

November 19.

Gentlemen: This woman presents herself with a large tumor of the right breast. I do not think it is a cancer, because a cancer very seldom reaches the size this tumor has without ulcerating; besides, as you see, the woman, who is fifty-two years of age, is yet well nourished, which certainly would not be the case if the tumor of two years' standing would be a cancer. I intend now to remove this tumor with the thermo-cautery and red-hot iron, and not in the usual (certainly more elegant) way with the knife. Think, gentlemen, what a large surface of nerves and vessels I would expose, and the blood which would be lost, by removing this large tumor with the knife—enough probably to prove disastrous for a woman of the patient's age, especially as we would not be able to obtain enough flap to close the wound without much tension. Gentlemen, I have removed now a number of various large tumors of the breast in cases not suitable to be removed by the knife, and I always found that the patients not only had no shock after the operation, but they retained their good appetite, were able even to be around some, and had no fever; conditions we seldom acquire after a bloody operation with the knife.

The patient being well anesthetized, as much as possible of the skin was dissected back from the tumor with the thermo-cautery. As soon as the loose connective tissue between the gland and pectorals major, etc., was reached, large spade-shaped red-hot irons were used; these worked their way comparatively rapidly, while the thermo-cautery proceeded but slowly.

During the operation the Professor alluded to the harmlessness of the large hot irons. It might be thought that by keeping the irons in so close proximity to the pleural serous membrane, great harm would be done to the latter; but there was no danger, as the Professor proved by holding his finger under the pectoralis muscle, and a red-hot iron over it; he did not feel it. Meat is a poor conductor of heat.

The operation was completed in 25 minutes. The tumor was a sarcoma; weighed 20 ounces. The amphitheatre was literally converted into a smoke-house, but the result of the operation was excellent. The patient, with a smiling face, was presented for the first change of dressing on the 23d. The patient had had no fever, had good appetite, and the wound was not discharging, but healthy granulations were pushing everywhere through the eschar. Such wounds are dressed with a layer of iodoform gauze, over which is placed a large gauze-back filled with wood-wool disinfected with $\frac{1}{2}$ pro mll. bichloride of mercury. The wood-wool is now extensively used in the Munich Allgemeines Krankenhaus. It is very finely planed pinewood, and absorbs discharges better than anything I saw before. It is especially superior to the various antiseptic absorbent cottons, of which only the layers next to the wound ab-

sorb, and then form an impermeable felt with the discharges, keeping the wound not drained but flooded, unless the wound is dressed twice daily, a point not desirable. This every one will have experienced who has used the cottons much. With wood-wool this is avoided; it may be left on the wound until filled. It keeps the wound perfectly aseptic, and is cheaper than any other material.

Radical Operation for Inguinal Hernia: Royal Suture.

November 20.—Gentlemen: You find the room this morning uncomfortably warm; but we are about to expose part of the peritoneum, which membrane is very much irritated by cold atmosphere. Two steam atomizers have disinfected the room for one-half hour with carbolic acid. You also see that my five assistants and I wear long white linen coats, of which we each have one dozen, so that we can take every morning a clean one; their light color makes us immediately detect any blood or dirt upon them; no excuse, therefore, for bad washing. Over the coats we wear rubber-sheet aprons, and sleeves of the same material. We have brushed our hands and nails, and now wash them with a half pr. mll. bichloride of mercury solution, and moisten our sleeves and aprons with the same. During the operation we shall use the spray. You may think it pedantic that I use the latter; and, in fact, many operators do not use it at all; but, gentlemen, I would not be contented in my conscience towards this patient should I leave out the spray, especially when I think that maybe twenty or thirty of you have been working in the anatomical room not more than twelve hours ago. Let me here tell you an experiment Pasteur made: He took some fresh urine, boiled it, and immediately put some of it in a test-tube, previously heated to a red-hot heat, and closed the tube with cotton. Some of the urine he poured in another tube prepared in the same way as the first; but the urine was poured in under carbolic acid spray, and the tube was closed under spray with cotton. The urine in the first tube was stinking after twenty-four hours, while that in the second had not changed in ten days. From this, gentlemen, you may infer that the spray is of some use.

This lad has a right inguinal hernia—not a bad one—of which he, however, desires to be relieved. I shall, therefore, perform an operation on him, which I have, since 1875, hunted up again out of the armory of old operations. I shall close the hernial sac as high up as possible by the so-called royal suture, and remove the sac below entirely.

This operation proved mostly fatal when it was practiced long ago; but since Lister's great invention, we may perform it without fear. If the cure is a permanent one, I am not ready to say; it may in some cases, but I doubt in all. However, on the same side the peritoneum is not likely to give way again.

The patient, whose scrotum and pubes had been shaved, and who had for the last twenty-four hours a carbolic acid compress over the inguinal region, was now well anesthetized. The inguinal region was yet brushed with a $\frac{1}{2}$ pr. mll. solution of bichloride of mercury. Then the Professor dissected down upon the hernial sac. It took some time before the sac was found, as the gut had

entirely slipped back into the abdomen. When found, it was separated from the tunica vaginalis, and vas deferens, to which it adhered. The adhesions were also broken up a little ways up the inguinal canal. Then the Professor made a small opening in the sac, and by passing his finger into the abdominal cavity, convinced himself that he was in the sac. The latter was now pulled down some. Sewed it together high up with catgut, and passed a strong ligature of the same material just below the suture. The projecting part of the sac, about an inch and a half, was then cut away with scissors. After this the scrotal cavity was well drained, the wound closed with catgut, and dressed with iodoform gauze and wood-wool back.

On December 8, this young man was brought again into the clinic; the wound had entirely healed. It was impossible at this time to pass a finger up into the inguinal canal; it filled up and closed by adhesions.

MEDICAL SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

BY J. H. MUSSER, M. D.

Thursday evening, June 14, Dr. Tyson, President, in the chair.

A Case of Chronic Bright's Disease.

K. T., æt. 35, admitted to University Hospital, July 17, 1878; single; a packer of goods; frequently exposed to draughts while in profuse perspiration; used tobacco to excess; once or twice a year he would spree. At twenty-two he had a chancre. (?) No secondary symptoms. Three times he had gonorrhœa. Always healthy prior to present illness; never had rheumatism.

The patient inherited a tendency to phthisis from both parents, and to rheumatism from his maternal grandmother.

The onset of the present illness was observed two years ago by a sudden night attack of dyspnœa. The dyspnœa continued for nine weeks, worse at night and preventing work in the daytime. Œdema of the feet and frequent micturition accompanied the dyspnœa. He improved, to have a relapse in four weeks of a month's duration, followed again by temporary improvement and a third relapse. From the latter he never rallied, Œdema, cough, dyspnœa, frequent micturition, and dyspeptic symptoms being constantly present. The cough was dry and attended by sub-sternal pain. The Œdema was general. When admitted to the hospital under the care of Prof. Pepper his condition was as above mentioned. During the July, August, and September following, the asthmatic attacks continued. In October they were relieved, but the anasarca became more pronounced.

It may not be out of place to say that the dyspnœa was very severe, and almost defied treatment. It presented the clinical characters of uræmic asthma, and was relieved only by inhalations of nitrite of amyl, or by hypodermatic injections of morphia. The anasarca was very great, and not relieved by diuretics, diaphoretics, or cathartics.

In October acupuncture was resorted to with temporary relief to the lower extremities and scrotum, its good effect lasting five days only, but being so marked as to encourage one in its use. During the following three months the punctures were made about fifteen times, and after each operation about three pints of serum would drain away. The latter part of December erysipelatous inflammation developed about the puncture and extended over it. During the progress of the inflammation, large bullæ would form, the bursting and continued free discharge of which caused an entire disappearance of the œdema of both legs. Relief was not only afforded by these operations to the œdema, but the attacks of asthma notably diminished in frequency and severity. January 8, two weeks after the inflammation of the right leg developed, sloughing took place. The sloughing was confined to the calf of the leg, was deep, and was attended with free *serous* discharge from the ulcers. In a few days a low typhoid state set in; he rapidly lost strength, and on the 7th of February died of exhaustion.

When these notes were taken (January 8,) the remaining features of the case were as follows: He was emaciated and anemic, and his skin was harsh and dry, his countenance anxious; appetite poor; flatulent dyspepsia marked; the bowels constipated; hemorrhoids; tympanitic abdomen; slightly enlarged liver; normal spleen.

At the apices of the lungs diminished expansion; flattening, impaired resonance, and increased fremitus at the left; moist crackling and sub-crepitant rales heard throughout the lungs. Apex beat of heart in sixth interspace one-fourth inch inside of nipple line; veins of right side of neck enlarged. Cardiac impulse moderately strong. At apex a low-pitched systolic murmur; muscular element lessened. At base pulmonary second accentuated. The width of the cardiac area of dullness was increased one-half inch to the left, and was not changed by full inspiration.

Urine contained albumen; amount varying, at times $\frac{2}{3}$, then $\frac{1}{3}$ bulk. Hyaline and numerous granular casts.

Ophthalmoscopic examination.—Small discs. Myopia. O. D. disc dirty gray, veins tortuous. No marked change in the color of the nerve; outlines misty, and is slightly swollen. O. S. disc same, but more marked. No hemorrhage in either eye. Diagnosed incipient neuritis.

Autopsy five hours after death. No rigor mortis; emaciated; commencing ecchymoses. Great fullness of the venous circulation.

Lungs.—Apices bound down by adhesions. Slight right hydrothorax. Base of left lung ant. and post. adherent. At left apex three or four areas of catarrhal pneumonia.

Heart.—Weight 21 ounces; left ventricle wall hypertrophied; mitral valve insufficient, admitting almost three fingers; its cusps thickened; one leaflet of the aortic valve slightly diseased; left cavities increased in size. Aorta atheromatous, a large patch especially one inch from the valves.

Liver enlarged, hard, congested. Kidneys small, congested, capsules adherent, relation of cortical to medullary substance normal.

Microscopical Examination.—Kidney showed decided interstitial nephritis, with fatty degenera-

tion of the tubular epithelium. Liver slightly cirrhotic and fatty. Muscular fibres of the heart slightly undergone fatty degeneration.

Aortic Valve Disease Due to the Combined Action of Strain and Rheumatism.

By J. H. Musser, M. D.

Neither the habits, the hygienic surroundings, nor the social conditions of Mr. C. K., from whom these specimens were removed, had any relation to the cause of his illness. As a laborer in a rolling-mill, his occupation might have had some predisposing influence on the localization of the disease, he being exposed to extremes of heat and obliged to do heavy lifting. The family history did not disclose hereditary disease. Withal in the past twenty years—at this noting he was aged 47—he had had frequent attacks of inflammatory rheumatism; and in 1878—four years previous to this account—he had an unusually severe attack, after which he recognized his present palpitation and indigestion, characterized by pain and vomiting. These symptoms increased in frequency and severity, and were often attended by œdemas of the legs. The last three years he was unable to work. Within the year lost in flesh and strength, and had several attacks of pulmonary congestion.

I abstract the condition on admission to hospital, December 1879, from notes taken as registrar. Slightly emaciated, sallow complexion, anæmic appearance, countenance of suffering, dry skin, cold extremities, ankles œdematous, muscular weakness, tremor on exertion, marked prominence of lower part of chest and bulging of præcordia, sternum pushed forward, lower half especially, giving pouter pigeon appearance. Impulse marked in normal cardiac area, and extending two inches to the left; epigastric pulsation; pulsation of veins of neck; apex beat in sixth interspace one inch outside of nipple line. No hepatic pulsation. A line drawn diagonally from the second right costo-sternal articulation to the fourth rib one inch from nipple line, and then vertically to the hepatic dullness, represents the right border of cardiac dullness. From the top of the third left rib, one inch from the sternum, a uniformly curved line extending to the apex beat, showed the left limit. By joining these lines with horizontal ones, the upper and lower borders are defined.

On auscultation at the aortic orifice, a strong systolic murmur, transmitted to the vessels of the neck, and a rough diastolic murmur, transmitted to the base and along the sternum, is noted. At the xiphoid cartilage, and at the apex systolic murmurs, differing in pitch, are heard, the latter also at the spine of the left scapula. Pulse small, feeble, compressible.

Cough, muco-purulent expectoration, are complained of, and the physical signs of bronchial congestion are observed. The appetite is poor; pyrosis and flatulence distressing; bowels constipated. Urine slightly albuminous; no casts.

Subsequent course.—With calomel and soda, and a liquid diet at first, followed by digitalis and quinia, the venous stases had disappeared, and the cardiac symptoms ameliorated within a month. After exposure to cold, internal venous congestions and œdema had supervened, and in five

days, January 20, 1879, he died of pulmonary congestion.

At the autopsy the lungs, liver, spleen, and kidneys were found characteristic of dilatation of the heart—congested, and with increase of connective tissue in the latter three organs. The heart presented very interesting lesions. It was enormously enlarged, weighing thirty-two ounces. The right heart was dilated; the ventricle wall averaged one-eighth inch in thickness; the tricuspid orifice was insufficient, and admitted four fingers. The left ventricle wall averaged one-half inch in thickness; the mitral valves were slightly thickened, and a few opaque patches were seen. The aortic valves presented a remarkable appearance. Two of them were fused together and were rigid, projecting in the lumen of the orifice—the other valve also assisting in narrowing the calibre of the opening by rigidly jutting outwards. The lumen was scarcely more than a slit. The coronary arteries were not closed, and were found at the bottom of pouches with calcareous walls. On one side the deposited calcareous matter of which the valves were composed, extended under the endocardium to the base of one of the mitral leaflets. Of course, the valves were covered by endothelium.

It is of interest to note that the mitral valves comparatively escaped the inflammatory storms, while the aortic valves were so markedly affected—contrary to the usual rule. It is suggested that a chronic valvulitis, or at least hyperæmia, might have been started by the strains incident to his occupation, and hence the valves readily invited acute inflammatory processes. The present condition being a secondary degenerative result thereof.

Thursday evening, June 28, the President, Dr. Tyson, in the chair.

A Specimen of Renal Calculus—Oxalate of Lime.

By J. H. Musser, M. D.

R. R., æt. 32, a stone-cutter, residing one year in Philadelphia, applied to me for treatment June 5, bringing with him a sample of his urine. It was bloody, and had been passing without pain during the twenty-four hours prior to this visit. Three months ago, without any cause, he was seized with pain in the left loin. The pain increased in severity, kept him from work, caused faintness, but no nausea or vomiting; did not radiate in any direction save transversely to a slight extent; lasted three days, and was not followed by hemorrhage. In the intervening three months he was in good health. A jar of the body or any movement did not increase the pain. It may be noted, but is rather irrelevant, that for ten or more years he has always had a weak back, becoming painful when stooping.

Twelve hours after the consultation the same localized pain recurred, and continued for twenty-four hours. Suddenly it was relieved, and the subsequent urinary discharges were clear. In three days he had a return of the pain and hemorrhage simultaneously. The pain increased in severity, and at the height of the paroxysm extended to the testicle and the head of the penis. The paroxysm was relieved by the passage of the calculus I show you by the urethra. The passage of the stone through the ureter was characterized

by the most agonizing pain, and frequent attempts to urinate. Microscopical examination of the first sample of urine showed the red color due to blood. A similar examination of his clear urine, as well as the bloody, proved the presence of urate of soda and crystals of the phosphates. The urine was acid. The diagnosis of renal calculus was not difficult, but the microscopical appearances of the urine led me to infer that the stone was composed of uric acid. With such idea the patient was put on alkaline treatment. The sequelæ proved that the solvent effect of such treatment was of no avail save from the diuretic action of the drugs. Morphia was given to relieve pain.

A portion only of the stone was received—an angular portion having been broken off by the patient. The portion weighs .06 gram. The exterior is tuberculated; the interior dark in color—bluish; the exterior lamina light brown. It is exceedingly hard. Chemical examination was made by Dr. Leffmann, who reported it to be an oxalate of lime calculus.

Hæmatoma in the Upper Portion of the Mediastinum, Producing Death by Suffocation.

Dr. J. T. Eskridge said that he obtained the specimen from a colored man, porter, aged thirty-two years. He had led an irregular life, but it was not positive that he had ever contracted syphilis. During the past winter he suffered from a severe cold on the chest, and was told by his physician that his heart was inflamed. With the exception of slight cough, unattended by any difficulty in breathing, he had considered himself in excellent health on June 10, 1883, when, after carrying a heavy trunk on his shoulder, from the first to the fourth floor of a hotel, at Cape May, he was seized immediately with great difficulty in breathing, and was compelled to seek the open window to prevent suffocation. During the next two days, while still remaining at the seashore, he suffered from several attacks of shortness of breath, each lasting from several minutes to an hour or more.

He was admitted to the Hospital of the Jefferson Medical College on the evening of June 12, about sixty hours after the occurrence of the accident. On admission his breathing was so labored that he was unable to speak. He was gasping for breath and bathed in profuse cold perspiration. Respiration 36, with greatly prolonged expiration; pulse 100; temperature 99.7°. Inhalations of amyl nitrite, and the hypodermic use of morphia and brandy, seemed to give relief. The attack lasted about twenty-five minutes. He slept well during the night, and was tolerably comfortable until 5 a. m., next day, when he had another paroxysm, which was promptly checked by amyl nitrite, morphia, and dry cups to the chest.

14th, a. m., Dr. Eskridge saw him for the first time. The patient was breathing quietly, and said that he felt comfortable. Pulse and temperature were nearly normal. Urine contained neither albumen nor sugar. No cardiac murmur was detected. Lungs were hyper-resonant at their apices. Loud moist bronchial rales were present throughout both lungs. In view of the man's former freedom from attacks of dyspnoea, he thought that he detected nothing capable of giving rise to so great interference with respira-

tion. The next two days no dyspnoic attack occurred, and he seemed to be doing well.

17th. His breathing was distressing for several hours. Nothing seemed to afford much relief.

18th. Severe asthmatic breathing came on at 6 a. m., and lasted in its worst form about six hours. Chloral hydrate gave some relief. After that paroxysm his breathing did not again become quiet. He died exhausted at 7 p. m. the next day. With the exception of occasional headache, he did not complain of pain at any time.

Section cadaveris was made by Dr. Parrott, the medical resident, the pathologist of the hospital and Dr. E. being absent from the city at the time.

Thorax.—Pericardial sac was completely obliterated by old firm adhesions between the pericardium and heart. The heart was rather soft, and both ventricles were relaxed, and contained considerable dark fluid blood. Valves nearly normal. Both pleurae were adherent to the upper portion of the pericardium, and the left pleura was everywhere adherent to the lung. Both lungs were emphysematous at their apices, and considerable lobular emphysema existed. Bronchial tubes were congested and contained considerable mucus.

A semi-solid, or rather soft oblong body, about two inches long by one and a half wide, was found lying upon the lower anterior surface of the trachea, imbedded in connective tissue, and firmly held by old adhesions. It occupied a position just above and behind the transverse portion of the arch of the thoracic aorta. Three of the rings of the trachea in the position where greatest pressure was exerted by the semi-solid mass presented a dark color, and one of the spaces between the discolored tracheal rings was nearly ulcerated through from the effects of pressure. On cutting into the tumor, it was found to consist of blood more or less clotted. The calibre of the trachea was greatly lessened at the seat of hemorrhage. No ruptured blood-vessels were found. No disease was observed in any of the arteries. Abdominal organs were nearly healthy in appearance.

Dr. Eskridge, in his remarks on the case, said numerous cases of rupture of the aorta, or of smaller blood-vessels, into the trachea, bronchi, oesophagus, or mediastinum, were on record; but in all of them, so far as his knowledge went, death resulted directly from loss of blood. The peculiarity of the case, of which he had given a description, was the formation of a hematoma in the mediastinum. In hemorrhages into that space, the blood usually gravitated to the lower portion of the chest, and the patient soon died from loss of blood. In the case he presented, however, on account of extensive old and firm adhesions of pleura, pericardium, connective tissue, and everything else in the upper portion of the mediastinum, a hemorrhage in that situation must necessarily have been circumscribed, and could have taken place only gradually by dissecting up the adhesions. He thought that the condition of the parts that prevented an extensive hemorrhage predisposed the smaller blood-vessels, especially the veins, of that locality to rupture. In view of the extensive alterations, by means of general adhesions, that had taken place at the seat of hemorrhage, it was not surprising that rupture of a blood-vessel should have occurred, when the parts

in the anterior region of the neck and upper portion of the chest were suddenly put upon the stretch, as occurred in the act of raising a heavy trunk from the floor and placing it upon the shoulder. From the specimen, as he obtained it, he was unable to say whether the hemorrhage had occurred from a rupture of the aorta or one of the smaller vessels, or from the bursting of a very small vessel that had become aneurismal. The tearing across of small veins would have been sufficient to give rise to the extravasated blood.

Congenital Fatty Tumor Beneath the Occipito-Frontal Muscle.

Fatty tumor beneath occipito-frontal muscle, presented by Dr. Nancrede. The tumor was simply presented on account of the rarity of such growths of foetal origin. The patient was a child aged 16 months. The growth was noticed at three weeks, and in consequence must have been of foetal origin, as it then was of the size of a bean. It presented none of the symptoms of a fatty tumor except a faint lobulation, the skin moving freely over it, and presenting none of the dimpling so common in lipomata. Its site was peculiar for a dermoid cyst, viz, over the right occipito-parietal region, yet its resemblance was so close that by exclusion it was considered to be a congenital cyst. Upon removal, it was seen to be distinctly beneath the aponeurosis of the occipito-frontal muscle. Microscopic sections, kindly made with the freezing microtome, by Dr. N. G. MacConnell, showed that the growth was a pure lipoma.

Adenomatous Growth Apparently Recurrent; in Reality an Outlying Portion of the Mamma not Removed at a Previous Operation.

Presented by Dr. Nancrede.

The above title really gives the essential points in the history of a patient aged 23 years, upon whom two operations had been performed for a supposed fibroma (adeno-fibroma) of the breast, which recurring after partial removal of the breast, the whole organ it was supposed had then been removed by another surgeon. Dr. Nancrede had opposed all operation at first, considering the breast was not really the seat of anything beyond a local induration after injury. He had removed the third growth, which, from its history and microscopic appearance, he was satisfied was the result of the irritating drag of the badly-placed cicatrix on a small portion of the breast tissue left at the second operation. The clinical lesson taught by this case was clear, viz., the freest removal of mammary growths.

Tumor of the Sciatic Nerve.

Presented by Dr. G. De Schweinitz.

The following case occurred in the hospital practice of Prof. John Ashhurst, jr., and it is by his permission that I exhibit the specimen. The patient from whom this tumor was taken is at present an inmate of the University Hospital, and gives the following history:

On June 16, 1864, owing to a gunshot wound of the right thigh, he sustained an amputation of that member at the junction of the middle with its lower third. The flaps sloughed, and a few weeks later a re-amputation became necessary. This stump healed, but was somewhat conical in shape, and never, from the very beginning, com-

fortable; being subject to frequent attacks of severe neuralgic pain. Within a year from the date of the amputation, a small lump, tender to the touch, was noted, situated posteriorly and a little to the outer side of the stump. The pains now became more severe and more frequent, and were of a "jumping" character, to use the patient's own language. The tumor increased slowly in size until three years ago, when its growth became more rapid, and at the same time the painful nature of the affection more pronounced, until lately the suffering was well-nigh unbearable. Finally the growth assumed the size which you see it now presents, and on the 12th of last month Dr. Ashhurst removed it, since which time the patient has been free from all pain, except such which naturally accompanied the healing of his wound.

The growth is an irregularly-shaped mass, about as large as a small hen's-egg, having an external envelope of adipose tissue, loosely held together by connective tissue. On section the interior is seen to be a somewhat elastic, rather dense-looking growth, of whitish color, over which pass a few yellowish fibres, probably strands of the sciatic nerve. Microscopic examination of the true

tumor mass shows an entire absence of any nervous elements, a section exhibiting fat cells, fibrous tissue, some spindle cells, and numerous free nuclei near the enlarged and dilated blood-vessels.

The tumor would, of course, be classed clinically as a neuroma, following amputation, while in truth its pathological nature is that of a fibroma. It is interesting that a growth causing so much pain should be without any demonstrable nervous endowment; and surgically it is further worthy of note, because its removal was attended with immediate and probably permanent relief to the patient, a desired result which is by no means always obtained by the excision of these growths.

Dr. Saurison, by invitation, made some remarks upon the bacillus tuberculosis, and exhibited a number of specimens. He said that he did not employ nitric acid in preparing his specimens, as it seemed in many cases to bleach out all the bacilli from the tissues, but formic acid in the proportion, acid. formic. 1 pint, alcohol 2 pints. It was a curious fact that the bacilli occurred in patches, while in other parts, apparently equally diseased, they were present in small numbers.

C. B. NANCREDE, *Recorder.*

EDITORIAL DEPARTMENT.

PERISCOPE.

A Simple Operation for Facial Neuralgia.

Dr. J. F. Henstis thus writes in the *Med. News*, December 8, 1883:

A. E. L., an old gentleman, past seventy, of fine constitution and very healthy in every respect, except being a sufferer from tic-douloureux, has consulted me several times in the last year for his complaint, and has taken the various remedies likely to benefit him, with very little relief. As he continued to suffer more and more, I advised him to let me operate on him as the only means of relief. But the neuralgia being general, affecting the branches of both the supra- and infra-orbital nerves, I could not promise him with entire confidence that an operation on the infra-orbital nerve would be sufficient, although that seemed to be most affected. The pains would dart all over the side of the head and face at the least touch, even of a hair of the head or beard, or from the impression of a breath of air, or even from the movement of the jaws in mastication. His suffering became so great and constant, and the neuralgic attacks so severe from attempts to eat, that he began to run down from sheer exhaustion from want of food and pain.

He was so weak at the time of operation, that it was a very important matter at his advanced age to make the operation as simple as possible, consistently with the hope of permanent relief. Therefore, discarding Carnochan's operation of trephining the antrum and following up the nerve beneath the orbit, and removing it; and Langen-

beck's slighter one, of dividing the nerve far back in the orbit with a tenotome, and drawing it out through the infra-orbital foramen, I merely cut down upon the infra-orbital foramen, and with a fine steel drill, such as dentists use, improvised of piano wire, drilled out the nerve in its entire length, as far back as the speno-maxillary fissure. The immediate effect of the operation was to abolish all sensation in the previously sensitive parts, and to enable him to use his jaws without suffering the darting pains he formerly had. And not only was the sensitiveness of the face relieved, but also that of the side of the head, showing that the trouble was in the distribution of the infra-orbital nerve, and that the affection of the branches of the supra-orbital was a reflex one. Barring some swelling of the face, he had no trouble afterwards. The wound soon healed, and he has been able to expose himself to the air, and eat with impunity, and now, although nearly two months have elapsed, he remains free from pain and is enjoying excellent health.

A Little-Known Cause of Deafness.

The *London Med. Record*, November 15, 1883, tells us that Dr. A. Ducan (*Rev. Mens. de Laryngologie*, etc., December 1883), has found a slit-like narrowing of the cartilaginous meatus very common amongst women of the lower classes, at about the menopause. He considers it caused by the fashion of wearing a handkerchief tied round the head, often with a band of hair lying between it and the ear. In nuns, the ears are also bound down by their headress. The result of the

pressure is that the auricle is gradually flattened against the head, and the tragus applied to the meatus like a lid. This has the effect both of retaining the secretion in the meatus, and of preventing the entrance of waves of sound.

A Scrotal Compressor.

Dr. G. Miliario describes the following instrument in the *Med. Record*.

Believing that support and pressure are the main factors upon which we are to rely for controlling and removing the effects of increased vascularity in scrotal diseases, I devised, many years ago, an apparatus having such ends in view. Its favorable reception by my professional brethren impresses me with the fact that the principle upon which its construction is founded is sound. Since its first introduction to the medical public, some improvements in construction have been made which I believe will increase its usefulness and extend its range of adaptability.

It is perhaps best to describe the perfected apparatus as it now is, and its mode of application, in order to come directly to the purpose of the present communication. The cut herewith represented gives a better idea of its construction than can be done by mere words. It is, in brief, a netted silk pouch for the scrotal organs, which can be compressed in any portion at will by shoving the encircling tapes in its meshes, and suspending the whole by means of bands to the waist. The penis is received in the circular opening in front, which opening can be enlarged in any direction for forced displacement of the organ without weakening the fabric. The posterior and upper edge of the pouch is provided with a cushion to modify pressure beyond the scrotum and against the perineum.

The first step in applying the apparatus is to secure for it close apposition to the scrotal organs. This is begun by taking the two ends of the upper lacings on either side (marked A), and by pulling uniformly on each the diameter of the upper part of the appliance is contracted and closed around the spermatic cord, above the testes, so as to prevent the latter escaping. The bandage being shirred snugly, is held in position by tying the lacings in bow knot under the penis. The next step is to similarly shirr and tie the lowest set of lacings, which closes and shortens the bandage below the testicle (marked C). This produces counter-action, and compression against the upper set of lacings, care being taken to exclude any fold of the scrotum.

The next lacings above the lowest set (marked B), which encircle the middle of the scrotal organs, should be shirred *only* snugly enough to be comfortable. In a few hours, according to the nature of the disease (as in the reduction of varicocele) the compression acts upon the absorbents, and the enlargement of the scrotal organs begins to abate. As this reduction of the scrotal contents progresses, the sets of lacings (marked A

and B) are to be tightened in order to maintain equable compression.

It is well known that in cases of epididymitis the disease must be arrested at once, or the epididymis will become indurated and closed, while the excretory duct of the testicle loses its function; in other large swellings, where rapid reduction is necessary to effect a cure, a bandage of large size containing more lacings becomes indispensable. In such cases the same rules for applying and shortening the bandage as above stated will be followed. They are manufactured of silk, linen, and cotton fabrics, mixed, and for ordinary purposes are made in three sizes, No. 1 being the smallest, No. 2 medium, and No. 3 the largest.

Nettle Rash.

We take the following practical points from an address on this subject by Dr. McCall Anderson in the *Brit. Med. Jour.*, December 8, 1883:

Diagnosis.—When the eruption appears in its typical form—in the shape of wheals which are pale in the centre and red at the edges—it cannot be mistaken for any other; and when it is due to the sting of an insect, the dark point in the centre of each wheal is characteristic; but when it assumes one of the less usual forms, the lesion being erythematous or papular (*Lichen urticatus*), or tubercular (*U. nodosa*), mistakes may sometimes arise, if due care be not taken. Such errors may, however, be generally avoided by noting the presence of the four following points, which almost invariably characterize the members of the urticaria group:

1. The rapidity with which the eruption makes its appearance.

2. The itching, burning, or stinging sensation to which it gives rise.

3. Its short duration, although the disease may be kept up indefinitely, owing to the occurrence of successive crops.

4. Its not being followed by desquamation.

Treatment.—The first point in the management of any case of urticaria is to endeavor to find out, and, if possible, to remove the cause or causes.

In acute cases, the eruption generally subsides within two or three days, when no treatment is adopted; but generally a sharp purge is of use, especially when, as in the majority of instances, the eating of some indigestible food, or digestive derangement, is at the root of the mischief; and, if we have reason to believe that such food is still in the stomach, as indicated by nausea, etc., an emetic of mustard, ipecacuanha, or sulphate of zinc, may be administered at the outset. In all such cases, stimulating food and drink should be avoided, and the diet should be of the simplest kind.

In chronic cases, a similar line of treatment should be pursued under similar circumstances, and, where we have reason to suspect that it results from the digestion being disturbed by some particular kind of food, the nature of which varies in different persons, owing to their peculiar idiosyncrasy, we may with advantage follow the advice of Willan, who wrote, "I have desired several persons, affected with chronic urticaria, to omit first one, then another article of food or drink, and have thus been frequently able to trace the cause of the symptoms. This appeared to be different in different persons. In some it was malt liquor; in others spirit, or spirit and water; in some, white wine; in others, vinegar; in some, fruit; in others, sugar; in some, fish; in others, unprepared vegetables." Like most other observers, however, he found that, in some cases, a complete alteration of the diet was not of the least avail. It would be quite out of place to refer to the means to be taken for the removal of the many other causes of this affection, as these must be treated upon general principles, and in the same way as we should do if they were independent of urticaria.

When no cause can be made out, or where the supposed cause has been removed, and the eruption continues to crop up, we must treat it empirically. We may, for example, try the effect, as Trousseau suggested, of the administration of sulphuric ether in doses of twenty to forty drops in water, or of quinine in full doses, or of arsenic, which is only exceptionally useful. But the medicines from which, perhaps, most is to be expected, are atropia and bromide of potassium; the former may be administered subcutaneously at night, or night and morning, the initial dose for an adult being $\frac{1}{16}$ of a grain (*e. g.* 5 minims of a solution of one grain of sulphate of atropia in 500 of water); the latter in doses of ten grains dissolved in water three times a day. In either case the dose should be gradually increased, either until the disease begins to yield, or until the superposition of the usual physiological effects renders it unsafe to push the experiment further. Occasionally, good results are obtained from the continuous current of electricity for ten minutes night and morning, one sponge (the positive pole) being

applied to the top, and the other to the bottom of the spine.

In obstinate cases, a complete change of air and scene and occupation is desirable.

Local treatment is generally resorted to, more with the view of alleviating the distress of the patient than in the hope that it will cut short the disease. The parts, for example, may be sponged with vinegar and water, or with eau de Cologne, or with a lotion of carbolic acid. An ointment containing chloroform or a mixture of chloral and camphor may sometimes be of service, and in exceptional cases not only temporary relief, but permanent benefit may result from the use of the tarry preparations, such as a lotion composed of equal parts of tar, soft soap, and rectified spirit.

A Method of Opening Psoas Abscesses.

Dr. T. F. Chavasse recommends the following in the *Lancet*, December 29, 1883:

The abscess was opened in the following manner: An incision was made immediately above the crest of the ilium, commencing at the edge of the erector spinæ muscle, and carried transversely outwards for four inches towards the anterior superior spine. Having divided its various structures as in colotomy, the anterior edge of the quadratus lumborum muscle was reached. The forefinger was then passed downwards and forwards on the iliacus until the tense and distended psoas sheath was detected. A scalpel introduced by the side of the finger incised the abscess sac, and the opening was subsequently enlarged by the introduction of a pair of dressing-forceps. This proceeding gave exit to a pint and a half of pus. Still keeping the forefinger in the wound, two large drainage-tubes were introduced into the abscess cavity, and left there.

Dr. C. says:

"You will naturally ask, Why open psoas abscesses pointing in the thigh above the iliac crest? The following are the advantages claimed for the procedure I have practiced in these two cases:

"1. The abscess is tapped, and the pus escapes at the most dependent point it is possible to obtain, and, as the patient lies on his back, the cavity drains itself without trouble or difficulty.

"2. When a sinus is thoroughly established, the drainage-tubes may be omitted at an early date, and any accumulation is unlikely to take place.

"3. The drain-hole is very near the diseased bone, so that the three or four inches of abscess cavity below this point becomes obliterated almost immediately after the operation. Hence a diminution of secreting surface.

"4. The pus escapes from an orifice removed from the genital organs, and the chance of the wound becoming septic is lessened.

"5. The antiseptic dressings can be applied and retained in position more readily than if the drain opening is in the thigh. Moreover, the pus will not so easily reach the edge of the dressing, and consequently it will not be necessary to make changes so frequently.

"6. From its situation, the patient is less likely to interfere with the dressing than if it be applied anteriorly.

"The disadvantages of making the incision in the position indicated are that the operation is slightly more difficult, some muscular fibres are severed, and there will be a little more bleeding than if the abscess be opened where it points on the inner side of the thigh; but all of these objections are trifling as compared with the satisfactory drainage. Even if the pus has burrowed beyond the thigh, and has reached the knee or a lower point in the extremity, the incision should still, in the first instance, be made in the back, and the abscess tapped there. Subsequently an opening may also be made where the pus is pointing, to allow the escape of the fluid accumulated below the principal draining orifice; this secondary incision will soon heal. The next best position to open a psoas abscess for antiseptic purposes is above Poupart's ligament, by means of an incision, as though about to ligature the external iliac artery. Having reached the transversalis fascia, by pressure below the pus can be made to bulge, or, failing this being accomplished satisfactorily, an opening large enough to admit a probe may be made in the thigh where the abscess is presenting, which when passed up under Poupart's ligament will indicate the whereabouts for the free incision in the deep textures. After the tubes have been inserted the orifice in the thigh closes. The drainage of the abscess in this position is not so good as by the other method; the opening not being so dependent, the tubes must be retained for a longer time, and more difficulty is experienced in getting a free escape of the pus. In one instance in which I operated by this plan upon a woman with a psoas abscess, the result of disease of the sacro-iliac synchondrosis, the fingers of the patient would wander under the dressings in spite of all protestations and threats, and the result was a septic condition of the wound, and eventually death."

The Single is Immediate Suture of a Lacerated Perineum.

Dr. T. Johnson Alloway, contributes a lengthy article with this title to the *Am. Jour. of Obstetrics*, January, 1884, which thus concludes as follows:

1. Examine carefully, with your eyes, every perineum after removal of placenta. If lacerated to more than a quarter of an inch, apply the suture.

2. Use one of Emmet's long, straight perineum needles, with a silk suture. By the aid of a holder, force the needle through the skin on the left side of the tear, half an inch from its edge, at any point between the beginning and end of tear, but the nearer to the beginning, that is, the higher up, the better will be the result. Now, with the two fingers of left hand in the rectum, press up the rectal wall and recto-vaginal cellular tissue, so that the needle can be rapidly, though steadily, made to glide beneath this tissue and over the rectum, hugging the latter as closely as possible, to make its exit at a corresponding point on the opposite, or right side. In tying the suture, avoid doing so too tight, as it is a good plan to allow for swelling, which generally lasts for some days.

3. Be sure that the needle in no part of its course makes an exit in the vaginal surface; if so, you will probably have a pus pocket.

4. The operation is very simple, and can be performed by any physician of ordinary experience.

5. The after-treatment consists in washing out the vaginal passage night and morning with any antiseptic solution the physician is accustomed to use. *But he must do it himself*; the nurse would be as likely to pass the tube below as above the suture, and kill all your joy. As regards antiseptics, I use in such cases a solution of corrosive sublimate $\frac{1}{2000}$ once in twenty-four hours, administered at night. I find this solution as handy and harmless as carbolic acid. Tell your chemist to make a 3ij. alcoholic solution of hyd. bichl., each drachm of the solution to contain seven and one-half grains of the salt. One teaspoonful of this mixture added to a pint of water will give, almost to a fraction, one part in one thousand. I have used this solution in cases of metria three times in the twelve hours for two consecutive days without any evidence of toxic effects from absorption. It is probably due to the formation of an insoluble albuminate of mercury, which seals up all breaks in the surface for a time.

6. The suture had better be allowed to remain in situ for nine or ten days. I am strongly in favor of the silk; the wire suture is liable to produce a bleeding point or two on removing it. This accident might prove troublesome from absorption, which is so active at this period of convalescence.

7. The nurse is the only assistant you will require, and is, of course, in your confidence.

Brain Exhaustion.

Dr. J. Leonard Corning discusses this subject in the *N. Y. Med. Jour.*, December 29, 1883, and enunciates as his principles of treatment, first, cerebral rest; second, increased general and cerebral nutrition; third, elimination of psychical irritation; and he thus carries them out:

The subject is secluded in a darkened room from ten to fifteen hours at a time, according to the amount of sleep which it is desired shall be had during the twenty-four hours. The amount of sleep is progressively increased by habit, moderate medication, and hydro-therapy, and no attempt is made to produce a sudden state of stupor by the reckless use of sedatives. When the patient awakes, as is usually the case, two or even three times during the hours set apart for rest, nourishment is administered, but always in a fluid and easily-digested form. Where difficulty is experienced in again falling asleep, resort is had in the beginning to limited medication. The few hours of wakefulness are devoted exclusively to some form of amusement—reading, writing, and even the mildest forms of mental concentration being absolutely prohibited. This, in brief, is the method from which I have already seen most happy results, and from the employment of which I hope and believe much good will in future be derived. It is hardly necessary to say that the problem of cerebral rest is essentially different, and presents many more difficulties than spinal rest. To give repose to the motor cells of the cord is comparatively an easy problem, and one which only exacts a permanent fixation of the motor apparatus for its solution, the consciousness or unconsciousness of the individual being only a matter of secondary importance. Rest,

however, for those cells, the function of which is the evolution of mind can only be obtained by a prolonged period of absolute unconsciousness; and this, as a matter of course, will often tax the patience and resources of the physician to the utmost. Perseverance and the utilization of the principle of habit will usually, however, render essential assistance.

Syphilis and Blindness.

We read as follows in the *Journal of Cutaneous and Venereal Diseases*, December, 1883:

Syphilis determines grave ocular lesions. It may produce blindness; it is a frequent cause of loss of vision; and this at any age—in infancy as well as in adult life.

All the membranes of the eye may be attacked with specific lesions, leading to destruction of the organ.

Most often the lesions are multiple; they rarely remain localized in a single membrane.

The ocular lesions of syphilis are most often indolent, and originate sometimes without the knowledge of the patient. Exception is made of iritis.

In the majority of cases, it is papillary atrophy which occasions the loss of vision.

Ataxia frequently shows itself in the syphilitic blind. Mixed specific treatment has considerable influence upon the ocular lesions of syphilis; a cure is quite frequent.—*Edward Binet, Th. de Paris, 1883.*

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—In a reprint from the *Alienist and Neurologist*, Dr. Talbot Jones gives a sketch of some recent acquisitions in nervous pathology. As a point of general interest, we quote what he says of syphilitic and of ordinary atheroma:

The distinctions between syphilitic endarteritis and atheroma are these: In the latter the caliber of the vessel is seldom diminished; in the former the lumen is lessened to a degree that may cause stenosis; in the latter only a few vessels are involved, in the former a large number; in the latter calcification may ensue, never observed in the former; and finally, the latter is incurable, which is not always true of the former.

—Hysteria has always been a mysterious disease, and in a study of it from the psychological point of view, by Dr. James H. Lloyd (reprint from the *Journal of Nervous and Mental Disease*), many curious facts are stated, and a moderately successful effort made to give them a consistent explanation. Bain and Maudsley are his chief authors.

—"The Esculapian" is a new medical journal published monthly in New York City by

Birmingham & Co. Its first number presents an attractive appearance.

BOOK NOTICES.

Fat and Blood. An Essay on the Treatment of Certain Forms of Neurasthenia and Hysteria.

By S. Weir Mitchell, M. D., etc. Third edition, revised, with additions. Philadelphia: J. B. Lippincott & Co. 1884, clo., pp. 164. Price, \$1.50.

The combination and systematic application of rest, massage, electricity, dietetics, and therapeutics, in cases dependent upon exhaustion or irregular action of the nerve centres, are set forth in this volume with commendable clearness and brevity. There is matter here which in many hands would have filled five hundred pages, but which in none could have been set forth with better effect than it now is.

The plan of treatment has been under trial for a number of years, and has succeeded in various instances in which no alleviation had been derived from the ordinary resources of our art. It can never become in extensive use, because it demands special surroundings, specially trained assistants—more than all, special traits and aptitudes in the physician himself—which must confine the scope of its usefulness very materially. Given these exceptional conditions, and its results are very surprising, as any one will see who reads the cases recorded in this volume.

With reference to this third edition, we should add that it has been largely rewritten, and a number of new points added.

Elements of Human Physiology. By Henry Power, M. B., F. R. C. S., etc., Philadelphia. H. C. Lea's Son & Co. 12mo., pp. 387.

This is another of the "Manuals for Students of Medicine," of the series of which we have heretofore spoken favorably. A rather close examination of this volume confirms us in the opinion that the series is an excellent one, and that this volume is not at all below the level of the others. It is neatly illustrated, the facts are presented lucidly, and the writer is thoroughly acquainted with his subject.

—Johns Hopkins University has provided itself with a new gymnasium, which was lately opened to the students and the public by cards of admission. The promotion of physical culture will be a part of the regular collegiate course. Dr. E. Mussey Hartwell, who is in charge of this department, delivered an address on Physical Training in Colleges and Universities.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

WOMEN IN MEDICINE.

While our County Society seems determined to exclude women from membership, and the profession at large is not over ready to extend the hand of professional friendship to them, we must, as fair-minded men, say, "Give them a chance."

There is, no doubt, considerable force in the argument that a woman is not physically capable of enduring the anxieties and the privations and the worriment incident to the life of a physician; but even if this be true, does that accord us the right to deny them admittance to the profession? Do we inquire into the physical characteristics of any male who desires to matriculate at our colleges? and should we do so with any more reason because a being wears petticoats?

We thoroughly realize the force of all the arguments that have been adduced against "women in medicine," but we cannot see that they afford ground either for refusing them admittance, or for offering them insults when they decide to join our ranks.

If a woman wants to drive a street-car or to run a locomotive or to engage in business, we say, "All right; go ahead; if you are capable, you will succeed." Why then should we not afford them the same opportunity in medicine, if they so desire?

We need not be particularly intimate with them if we so elect; but we have no right, as gentlemen, to openly insult them, as has been repeatedly done by thoughtless young students in the lecture-rooms of some of our hospitals, where these women students resort for clinical teaching.

Recently, at the Philadelphia Hospital, in this city, some thoughtless young fellows were amusing themselves at the expense of the female students in attendance, when Miss A. M. Fielde, one of their number—one of the most widely-known and eminent missionaries in China—arose on the inspiration of the moment, and amidst instant and most respectful silence, spoke as follows: "Gentlemen: I have been for eighteen years a missionary in China. The Chinese have no medical science, and superstitious rites are chiefly relied on in the treatment of disease. All the

people are in need of medical aid, but the *women* are the *neediest*. A Chinese woman would under no circumstances go to a male physician for the treatment of any disease peculiar to her sex. She would be prevented by her own womanly delicacy, and by all the notions of modesty held by those around her. She would suffer life-long agony rather than violate her sense of propriety. Her father, her brothers, and her husband, would even let her die, rather than allow her to be treated by a male physician. Full of sorrow for the sufferings of these women, I have been looking in Christian America to see what hope of help for them might be here. I have been glad to find that in some of our great medical schools earnest and self-sacrificing women are fitting themselves for a work of mercy in Asia and other lands. Unless such women learn to do such work well, there is no physical salvation for those afflicted ones. And in behalf of those women, who have no medical care while they so sorely need it, I ask from you the courtesy of gentlemen toward ladies who are studying medicine in Philadelphia." The whole class at once applauded, and a gentlemanly young student arose and informed the ladies that hereafter they would not be molested. We say again, if women want to study medicine, we have no right to say nay, and it is our duty, as gentlemen, to discountenance anything that may seem like offering an insult to a woman.

A POPULAR KNOWLEDGE OF PHYSIOLOGY.

From time to time the question has been discussed whether it is well that the public should be instructed in physiology, and both sides of the subject have been maintained with much force and logic. It is a problem possessed of more than passing interest, for on the side of those who argue in the affirmative there are many strong points.

The practical value of hygiene to the masses is really based upon an acquaintance with physiology by the masses.

If the public do not know what nature intends their various organs to do, how can we expect the

public to know how to so treat these organs that they can do what they are destined for?

The age of blind faith has gone by; and the inquiring mind of man wants to know why he should be directed to do so and so.

If we tell him that certain acts are detrimental to health, he wants to know why! and when we answer that they will derange the functions of certain organs, he wants to be informed as to the nature of these functions.

It is true that a knowledge of the disastrous results of improper living does not, oftentimes, deter human nature from these errors, as the reckless lives of so many physicians so amply testify; yet with a knowledge of physiology they are prepared, of their own free will, to accept the consequences of their wrong-doings, and cannot plead "ignorance of the law."

A knowledge of the physiology of the sexual organs would prevent many a young girl from receiving a shock to her nervous system at the unexpected and startling flow of blood at the commencement of her menstrual life, that no doubt sometimes is the starting-point of some serious and perhaps irremediable nervous disease.

It is true that physiology is taught in some schools; but it seems to us that it should form a very important portion of the education of every boy and girl.

There is no necessity of going into the little details of what might be called minute physiology, but the gross or general physiology of our various organs and parts, the why each organ exists, and the purpose it ought to serve in the economy of life, are surely subjects with which every human being ought to have some considerable familiarity.

Such knowledge need not and would not redound to the detriment of the physician; on the contrary, we imagine that it would augment his practice; for did the people but know how insidious are the beginnings of disease (and this they would know, if they were familiar with physiology), they would much more eagerly and more frequently consult the physician, and would be much less apt to trust to the blind and unreasoning faith in the quack medicines, so prevalent

now, principally on account of the mystery that surrounds everything pertaining to the science of medicine. Remove this mystery, let the public understand more about the approach and march of disease, and the rational methods of cure, and some of the millions that annually flow towards the patient medicine venders, will find their way to the reputable and honorable physician.

NITRO-GLYCERINE AND THE CHLORIDE OF GOLD AND SODIUM IN ALBUMINURIA.

The paper recently read before the Philadelphia County Medical Society by Professor Roberts Bartholow is well worthy of the widest publicity, for it constitutes one of the most important additions to our therapeutic resources that we have noted for many a long day.

Our weapons have hitherto been very inefficient in the warfare with this condition; and should these drugs prove to possess the powers that this distinguished author attributes to them, we will have, indeed, cause to be very much pleased.

He would use nitro-glycerine, in doses of one minim of a centesimal solution (one minim of the pure drug to 100 minims of alcohol), every three or four hours, in acute cases immediately after the subsidence of the acute symptoms, and in chronic cases at all periods. Chloride of gold and sodium is indicated in the sub-acute and chronic cases, especially the latter. The earlier it is given the better, if structural changes are to be prevented or arrested. The good effects to be expected from it will depend necessarily on the extent of the damage already inflicted on the kidneys.

The usual dose is one-twentieth grain, twice a day, but this may be much increased, if necessary. At the outset, one-tenth grain may be given; in a week the dose should be lowered to one-fifteenth grain, and after a month the regular dose of one-twentieth grain should be steadily pursued, with occasional intermissions. Indigestion, gastralgia, and colic pains, nausea or diarrhoea, are occasionally caused by it; and, if so, the quantity administered must be reduced. It is usually borne without any discomfort, but after

prolonged administration, salivation, weakness, emaciation, trembling, and other nervous phenomena may occur possibly.

This valuable paper will be published in full in our pages.

THE DRAINAGE OF BOSTON.

The city of Boston has made a most marked sanitary advance in the method of disposing of its refuse.

The system consists essentially in an intercepting sewer, which receives all the waste from the various sewers of the city, by which it is carried to a point at which large pumping engines are located; with their aid the accumulation of sewage is artificially propelled, and by the aid of a system of dams, so to speak, it is discharged into the sea at ebb-tide. Practically this plan works very well in Boston, but it is only adapted to sea-side cities. It transpires that before the flood-tide sets in the sewage is miles out at sea. But this system seems very wasteful. When we remember that the sewage that is emptied into the Thames from one output alone, is sufficient to make annually 650,000 tons of manure, it seems a pity that this enormous mass of valuable material should be lost to the soil.

Again, it may transpire that, in time, the water of Boston harbor may become so contaminated by this constant enormous outflow of waste, that the fish therein may be rendered unfit for food, and since they *will* be caught and eaten, they may prove a fruitful source of disease. The method in vogue is, no doubt, the very best in use in any of our large cities, and the sanitary spirit of the people of the "Hub," that made its accomplishment possible, is most commendable and worthy of imitation; but the query arises, whether any system of drainage that does not restore human refuse to the soil from which it came, will not be ultimately found more or less faulty.

—The *Sanitarian*, after a year's experience as a weekly publication, announces its return to its old form as a monthly, but enlarged to ninety-six pages, and with improved type.

NOTES AND COMMENTS.

Resection in Fracture.

Dr. James Patton (*Glasgow Med. Jour.*, January, 1884) highly lauds excision, under antiseptic precautions, in the treatment of compound fractures, and after relating the histories of three cases, he thus concludes: "If there be any class of cases which has been brought forward over and over again to prove the value of aseptic surgery, it has been that of compound fractures. The above cases show to what extent aseptic surgical interference with bony structures may be made, and productive of the happiest results; and it seems to me that resection has not yet attained that general consideration in the treatment of severe compound fractures, and even of some rare forms of simple fractures, which ought to be given to it. Many limbs might be saved in this way, which otherwise would be amputated. Of course there is bound to be shortening of the limb, but not more than the use of a high-heeled boot will make good. There is one thing which I have found of enormous advantage in the treatment of severe compound fractures, and that is the moulding of an iron bar to the contour of the limb, of sufficient strength not to yield when the wound is being dressed.

"I have given these cases, not for the purpose of lauding the aseptic treatment of fractures (as it is now too late in the day to do so), but more for the purpose of showing what beneficial results may be obtained from resections conducted on aseptic principles."

A Spindle-Cell Sarcoma of the Rectum.

The Philadelphia correspondent of the *Boston M. and S. Jour.* writes that Dr. R. J. Levis recently operated upon an unusual case at the Pennsylvania Hospital. A man, forty-three years of age, gave a history of difficulty in defecation, in its origin dating back some three years. Of late he had been obliged to resort to purgatives and enemata in order to secure evacuation. Hardened feces were sometimes the cause of some bleeding from the rectum. Two years ago he suffered with an inflammatory trouble in the perineal region, and with retention of urine. One year ago he detected a small tumor within the rectum by the introduction of his finger to relieve the tenesmus. It was then the size of a walnut. This tumor, when he came under observation, had attained the size of a fetal head. By an effort, the mass could be made to appear outside the sphincter ani. Upon examination the growth

was found to be beneath the mucous membrane of the bowel, having its origin in the submucous structures of the bowel to which it was attached, or in the connective tissue. Dr. Levis grasped the tumor with strong hooks, and pulled it downward, and easily enucleated it. After removal it was found to be rather dense and elastic; it was nearly three inches in diameter, and weighed twenty-four ounces. It was pronounced a spindle-celled sarcoma upon microscopic examination, making it one of the rarest growths in this situation.

Quebracho in Dyspnoea.

Professor Da Costa has had some very satisfactory results from the treatment of dyspnoea by quebracho. In a recent lecture he said that in his experience it had been especially serviceable in two classes of cases: (1) in purely nervous asthma he had found it to be invaluable; (2) in cases which have been rather loosely called cardiac asthma, cases in which a heart lesion has produced failure of cardiac contraction and consequent congestion of the lungs, he had also known it to be very useful. It may serve as a cardiac tonic, or may do good solely by its action upon the respiratory centre in the medulla. Whatever may be the explanation, however, it gives wonderful relief in appropriate cases. The way in which he gives it is the fluid extract in doses of twenty minims every hour, gradually increasing the amount, some patients requiring as much as a drachm before relief is obtained. The good effects are observed usually after two or three doses have been taken. The taste is well covered by using equal quantities of the French syrup of red orange and water as the vehicle. In this form it usually agrees with the stomach. As the respiratory symptoms are relieved, the remedy may be given at longer intervals.

Treatment of Mammary Cancer.

The *Boston Med. and Surg. Jour.*, December 27, 1883, tells us that Küster, in a paper read before the Twelfth Congress of the German Surgical Society, advocates the careful dissection and removal of the contents of the axilla in every operation for cancer of the mamma.

This recommendation, which is not new, gains weight from his report of the careful microscopic examination of the glands in a number of cases where they were seemingly unaffected, and in which, nevertheless, a commencing cancerous change was found in them.

To show the effect of his thorough operation in preventing recurrence, Küster states that, of sixty

women whom he had thus operated upon prior to three years ago, thirteen, or 21.66 per cent., remain well.

Gussenbauer, Langenbeck, and Esmarch spoke in favor of this thorough operation, and Esmarch even declared that when the glands were intimately adherent to the vessels and nerves, and yet there was no appearance of the disease in other parts, he was in favor of disarticulating the arm to permit of thorough removal; and he stated that the only case in which he had done this recovered, and has never had a return of the disease.

The Word "Malaria."

A physician in Tennessee writes us: "Is it not time that our profession should drop from its vocabulary the word *malaria*? Its proper meaning is simply *bad air*, and it fails to express the modern idea of the diseases attributed to it."

It is quite true that the word by its etymology means simply "bad air;" but a great many words—the vast majority, in fact—mean in modern usage something very different from their primitive signification. It is of no moment, for example, that *lunacy* means literally *moon-struck*, that *hysteria* means an affection of the womb, that *scrofula* means *sow's evil*, and the like. If the term has a current modern signification, clearly defined and understood among scientific men, that is all we should ask. "*Malaria*" means that subtle substance which pervades the atmosphere of certain localities, giving rise to diseases characterized by remittance or intermittence of symptoms. Whether this is an animal germ, a vegetable spore, or a chemical poison, has not yet been conclusively shown. Until we can get at the facts, this word will answer as well as another to conceal our ignorance.

Exophthalmos with Loss of Sight and Aortic Insufficiency Benefited by Iodide of Potassium.

To the Clinical Society of Maryland (*Maryland Med. Jour.*, December 29, 1883), Dr. Bermann related a case of a colored woman, *æt.* 50, who has lately lost the sight in her right eye, within the space of two days. There is occasional pain in the eye, and it protrudes very much. Ophthalmoscopic examination throws but little light on the case; there is some venous congestion of the disk, the outlines of which are a little dim. Auscultation of the chest reveals a decided insufficiency of the aortic valve, and consequent hypertrophy of the left ventricle. There is also pulsation in the neck. There is no evidence of syphilis, and the

patent denies it; but there being no clue to the nature of the case, she was put upon iodide of potassium, gr. viij, three times a day, and the results have been most satisfactory, the exophthalmos having decidedly diminished and the sight improved. At the beginning of the treatment she could not count the fingers, being able only to distinguish their movement; now she counts the fingers at twenty feet.

Hypericum (St. John's Wort) for Bed Sores.

Dr. Herbert L. Snow recommends it in the *Brit. Med. Jour.*, December 8, 1883, saying: "My attention was drawn to this remedy, some years ago, by the friends of a patient afflicted with bed-sores. From the slight experience of two cases I can strongly recommend it; it appears to induce healthy granulation and a more or less rapid cure, in a manner which we should vainly look for from alcoholic or balsamic preparations—and this without any smarting from the application. The compound oil of hypericum, which alone I have used, is sold by Mr. Garrad, chemist, of Leamington; I have vainly tried to procure it in London. A recipe in my possession directs that bottles be filled half-full with the flowers of the St. John's wort; olive oil is then to be added, and the bottles are to stand in sunshine for a few days, till the oil becomes of a deep-red color; it is then fit for use, and may be either drawn off at once, or left till required. It is merely brushed over the sore, two or three times daily, with a feather."

Effect of the Atmosphere on the Voice.

Our English exchanges inform us that Dr. Moffat delivered a lecture lately in Glasgow, on voice training by chemical means. Dr. Moffat maintained that the presence of peroxide of hydrogen in the air and dew of Italy had some connection with the beauty of the Italian vocal tone. A series of illustrations by people taken from the audience, who inhaled a chemical compound made to represent Italian air, were largely satisfactory—a full, clear, rich, mellow tone being produced by one application. Several gentlemen present gave their favorable opinion of the new idea. Dr. Moffat's own illustrations were quite unique. Taking what was originally a voice of power and resonance but destitute of intonation, he showed by chemical means this could become a tenor of great range. Some twenty notes, ranging from the lower to the higher register, were sung without any effort by the possessor of a voice of this character.

The Poison of Rheumatic Fever.

Quite a lengthy article on this subject by Dr. David Thomson thus concludes in the *Lancet*, December 29, 1883:

"I am inclined to conclude that the poison of rheumatic fever is derived from without; that, though it arises under circumstances incompatible with the belief that it can be of malarious origin as usually understood, yet it is not improbable that it may be a terrestrial aeriform emanation. And we have ample reason to show that, whatever be the nature of the poison, salicine and its compounds exercise such a beneficial action over it as to entitle them to be called specifics. Nor is the method employed by some, of giving it with a half belief in its efficacy, in small doses, of any utility; indeed, it is worse than not using it at all, for while it affords no relief to the sufferer, it at the same time brings discredit upon a remedy of great value."

The Code of Consultations.

There has been formed in New York City a new County Medical Society, the members of which agree to respect the Code of Ethics with reference to consultations. The position in favor of the new code taken in the New York State Society is principally due to the influence of the members of the City Society, which has led in the movement of free consultations. The new organization is intended to offset this, and has begun its labors by canvassing the physicians of the State. Out of 5219 doctors, 2442 favor the old code, 943 the new, 210 no code, and 1611 have not been heard from. This shows that a decided majority of the physicians in that State are opposed to this new device. In fact, as we have before shown, it was started by a few specialists for their own purposes of gain, and with no sort of reference to the benefit of the profession at large.

The Advantages of Precaution Against Infection in Operations.

This advantage was never more forcibly illustrated than in two cases reported by Dr. Francis Minot (*Boston M. and S. Jour.*, January 17, 1883), of uterine polypi in which operative interference was resorted to. In the one, the woman died, and it was found after death that there was a case of erysipelas in the adjoining room. The second patient, who entered the hospital at the same time, was carefully isolated, and recovered without an untoward symptom. It is well to bear ever in mind that the uterus is a very common channel for the entrance of disease germs, and that when-

ever we expect to have a *raw* uterine surface, it behooves us to take especial care that no germs are in the vicinity.

Too Many Doctors.

The facility of graduating in medicine is so great in this country that the profession is desperately overcrowded. Quite recently a writer in a western journal has undertaken the apparently hopeless task of endeavoring to discourage young men from entering it. "There are now," he says, "90,000 physicians and surgeons in this country, or one to every 500 inhabitants. Indeed, every cross-roads where a grocery or a blacksmith-shop is located, has also the shingle of at least one medical practitioner, and in most cases more than one."

All this is sadly true, and the result of it is that many a doctor derives from his profession not more than a skilled mechanic from his trade, without the latter's chance of increase.

Conium in Malarial Diseases.

Dr. Richard C. Newton tells the *Med. Record*. January 19, 1884, that during the summer and spring of this year he has used repeatedly the following prescription:

R.	Ext. conii fld.	℥ ij.
	Ferri perox.	℥ ij.
	Spts. vini gallici.	℥ ss.
	Quin. sulph.	℥ ss.
	Syr. simp.	℥ ij.
	Ol. menth. pip.	℥ ij.

M. Sig. 3 j. q. four hours until two hours before chill is expected, then q. two hours for two or three doses, then q. four hours.

To children it has been given very successfully by doubling the amount of syrup.

Sierra Salviæ in Remittent Fever.

We have recently noted that it is generally believed that there are certain cases in which quinine is not admissible. In such, Dr. Francis A. Evans (*Nashville Jour. Med. and Surg.*, December 1883,) says that he has had very satisfactory results from the use of *sierra salviæ*. He uses it in the form of fluid extract, in doses of four drops every two hours, combining it with tincture veratrum or tinct. nux vomica.

Helenine and Its Therapeutic Application.

Dr. Valenzuela has had very good results, which he publishes in the *Bull. Gen. de Therap.*, December 15, 1883, from the use of helenine in diseases of the respiratory apparatus, such as

broncho-pneumonia and tuberculosis. It has also proved serviceable in whooping-cough. It has a general tonic effect. The dose is $\frac{1}{2}$ of a grain ten times daily. It may be used by inhalation.

Iron Hypodermically in Anæmia.

Dr. J. M. Da Costa has been using hypodermic injections of iron with good results in a case of combined malarial poisoning and lardaceous disease of the viscera. He prefers a double salt produced by the addition of pyrophosphate of iron to a solution of citrate of sodium. Two grains of the salt, in this form, are given every day, varying the points of puncture, but generally administering it under the skin of the extremities; in this form no abscesses have been observed. With other solutions of iron, including dialyzed iron, abscesses were quite common even with every precaution as to the cleanliness of the syringe.

A Caution About Belladonna Plasters.

One would hardly suppose that serious results could ensue from the application of a belladonna plaster, yet Dr. Martin J. Fleming reports a case of well-marked belladonna poisoning, relieved by opium treatment, in the *Medical Record*, January 19, 1884, caused by the application of a plaster to a back that had been somewhat denuded by the use of an irritating liniment. The case suggests the advisability of cautioning patients against applying such plasters over an abraded skin surface.

More About the Mullein Plant in Phthisis.

We recently noted that Dr. F. J. B. Quinlan had reported a considerable increase in weight in a patient in the pre-tubercular stage of phthisis under the use of mullein. We find a supplemental note in the *Brit. Med. Jour.*, January 5, 1884, from which we learn that this same patient only gained seven pounds eight ounces under the use of cod-liver oil, in the same space of time in which she had gained twelve pounds eight ounces under mullein. Her cure was complete, and the respiration over both lungs is normal.

Dirt Mistaken for Disease.

It was supposed by Dr. C. Mettenheimer (*Schmidt's Jahrb.*) that an old woman of eighty-seven was afflicted with ichthyosis. The foot and outer side of the thigh were covered with brown, horny scales, nearly an inch in thickness, resem-

bling alligator's skin. Warm water and a weak solution of caustic soda demonstrated that these scales were merely the dirt that had been accumulating for twenty-five years, and revealed perfectly healthy skin below.

A Sign of Internal Cancer.

Prof. Verneuil (*La Semaine Med.*) calls attention to the fact that when hemorrhage frequently occurs from the ulcerated surface of an external cancer, it generally indicates cancerous disease of some internal organ, most usually the liver. This occurrence should therefore make us chary about resorting to the knife, until we have thoroughly examined the internal organs.

SPECIAL REPORT.

NO. XV.—OPHTHALMOLOGY.*

BY C. S. TURNBULL, M. D.,

Oculist to the German Hospital, Philadelphia.

(Continued from page 126.)

Hydatid Tumor of Orbit. Ophth. Hosp. Rep., vol. x. 3, p. 301. Lawson describes a cystoid tumor. The patient had complained of diplopia for seven or eight years, until sight was almost destroyed. Exophthalmus then gradually formed. Lawson removed the tumor; recovery without accident.

Étude Clinique et Anatomique sur un cas d'Angiome Caverneux Enkysté de l'Orbite. Laboratoire de la Clinique Ophthalmologique de Lyon, Arch. d'Ophth., vol. ii., No. 3. Eloni removed an encapsuled cavernous angioma of the right orbit the size of a hazelnut, which had developed in a woman of fifty-two, in the course of three years, after a painful inflammation of the eye, as she stated. There was moderate exophthalmus. The tumor lay under the right external rectus, so that tenotomy was necessary in order to detach it from its base. Eight days after the operation, the optic disc appeared white and the blood-vessels thin. Eloni attributes these symptoms to hemorrhage into the sheath of the optic nerve, and to division of some ciliary nerves.

Angiome Caverneux de l'Orbite. Gaz. d'Ophth., No. 6, 1882. Camuset, in a man of thirty-two, observed the development of right-sided exophthalmus, in the course of a year, accompanied by

*From the Progress of Ophthalmology During the Second and Third Quarter of the Year 1882, by H. Magnus, of Breslau, and Others.—*Archiv. Ophthalm.*, vol. xii., No. 1.

symptoms of inflammation and diplopia. It increased during the following eight years—sometimes increasing, sometimes diminishing. The outer canthus was split and the conjunctiva incised, when after dividing the orbital fascia a round tumor became visible, which could easily be detached from its attachments to the external wall and apex of the orbit. The lachrymal gland was removed with it. Recovery within a week. The tumor proved to be an angioma.

Echinococcus in the Orbit (From the Ophthalm. Clinic of Prof. Hirschmann in Charcow.) Wratsch, No. 19, 1882. Barabachew observed the sudden development of exophthalmus in a peasant girl of twelve; motility was checked in every direction; the cornea necrotic. Upward and inward of the globe there was a tumor adhering to the periorbital, which did not fluctuate, and made the impression of a firm neoplasm. Besides amaurosis, there was severe headache. The tumor had been growing for a year. The eye was enucleated, and an echinococcus tumor removed, of the size of a walnut.

Pulsating Exophthalmus; Anterior Venous Aneurism of Right Internal Carotid; Ligature of the Common Carotid. Wratsch, No. 13, 1882. Sklifassowsky, in a man of forty-five, found œdema of the lids and conjunctiva, exophthalmus, wide pupil, and a subjectively audible murmur; the cornea was dull; $V=0$; and the eye immovable. The sound eased when the carotid was compressed, but the exophthalmus remained. Digital compression was tried for a week, but failed. All the symptoms, however, disappeared after ligating the carotid artery. Amaurosis continued, and opacity of the lens developed.

Un Caso di Tenonite Primitiva. Ann. d'Ottalm., May, vol. xi., p. 170. * Ramfold observed a case of primary tenonitis, which begun with chemosis, exophthalmus, and complete immobility of the eye, sight remaining intact. Later, exudative choroiditis set in, destroying vision. The symptoms of irritation disappeared after the conjunctiva had ruptured at the insertions of the superior internal, and inferior rectus muscles, and a quantity of thin pus had been discharged.

Some Thermometric Observations in a Case of Traumatic Diphtheria of the Orbit. Philadelphia Med. Times, July 29, 1882. Heyl reports a case of enucleation for melano-sarcoma. Diphtheritic inflammation of the remaining conjunctiva followed, during which the temperature in the orbit rose to 100° .

Conjunctivites Simples, leur Nature, leur Traitement. Rec. d'Ophth., Vol. III., No. 7, p. 410.

Brachet discusses conjunctivitis in general, and

calls attention to the necessity of treating co-existent affections of the cornea, the lachrymal apparatus, etc. He speaks besides in particular of phlyctenular and lachrymal conjunctivitis. The latter name Galezowski has applied to a form of conjunctivitis produced and kept up by stenosis of the lachrymal duct.

On Credé's Procedure for the Prevention of Blennorrhœa Neonatorum. Arch. f. Gynak., Vol. XIX., p. 258.

Bayer has employed Credé's procedure for the prevention of blennorrhœa neonatorum, the instillation of a two per cent. solution of nitrate of silver, in the Lying-in Institute at Stuttgart, and in consequence did not see a single case among 361 children.

On the Prophylaxis of Blennorrhœa Neonatorum. Correspondenzbl. f. Schweizer Ärzte, 1882, No. 7.

Horner has treated 468 cases of blennorrhœa of the new-born in the course of twenty-two years. In 122 there was severe inflammation of the cornea; in 35 it had already perforated; in 38 the cornea became affected during treatment. Of the last-mentioned, 14 healed without produced maculæ of consequence. Horner is opposed to the procedure of Credé, and to cleansing the eye with a two per cent. solution of carbolic acid in private practice, as the midwives pour the solution directly into the eye and cauterize the cornea. The midwives, however, should be forced to observe the precautions necessary to avoid blennorrhœa of the new-born, by irrigation of the vagina of the mother, by cleansing the instruments and hands, and to give immediate notice in case the eyes become affected.

Traitement de la Conjonctivite Blennorrhagique. Gaz. des Hôp., April, 1882.

Abadie, in blennorrhœa, both of new-born and of adults, cauterizes the conjunctiva from the first day of inflammation with a 3-4 per cent. solution of nitrate of silver every twelve hours. Ice applications must be made besides, if possible, together with a solution of boracic acid.

Ophthalmic-Blennorrhœa Neonatorum. Hospitals tidende, June 21, 1882.

Meyer gives the percentage of blennorrhœa of the new-born in the Lying-in Hospital at Copenhagen. He recommends Credé's procedure as the best preventative.

The Micrococci of Blennorrhœa Neonatorum. Centralbl. f. Prakt. Augenhk., 1882, p. 134.

Krause succeeded in obtaining the micrococci of blennorrhœa pus by impregnating mutton blood-serum with it and treating it in the moist chamber and the incubator. They are always

attached to each other in the secretion in dumb-bell shape. The result of inoculation of animals with the pure material was negative; in a new-born rabbit only profuse suppuration of the conjunctiva set in.

Boracic Acid for Granular Lids. N. Y. Monthly R., February 1882.

Minor recommends the use of boracic acid in form of powder in trachoma, especially in fresh granulations.

Quelques mots à propos du Traitement de la Conjonctivite Granuleuse. Ann. d'Ocul., May, June, September, October, 1882.

According to Abadie, the inoculation of blennorrhœic pus is only indicated in trachoma, when the conjunctiva is still really inflamed, but not when the inflammation is over, the conjunctiva atrophic and the cornea thin, leucomatous or staphylomatous. Five Lustra of Ophthalmological Practice, p. 92.

Mooren, in inveterate pannus, inoculates blennorrhœic pus without fear, as a reliable means of obtaining a cure. The secretion obtained from an otherwise healthy new-born child, affected with blennorrhœa, is the best.

Du Pannus et son Traitement par Inoculation Blennorrhagique. Lille, 1882.

Vilfroy advises the inoculation of blennorrhœic pus in dense pannus of both eyes only, as there is then no danger to the cornea.

L'Ophthalmie Purulente Factice Produite au Moyen du Jequirity, on Liane a Reglisse. Ann. d'Ocul., 1882. July-August; Rev. d'Ocul du sud-ouest, Vol. iii, No. 9, p. 192.

Wecker was informed by a gentlemen who formerly had suffered from trachoma, that he had obtained an excellent result in himself by the use of Jequirity (*abrus precatorius*). The substance is used in Brazil for trachoma, with excellent results. Wecker makes use of it in diphtheria, granulations and pannus of long standing, in order to produce rapid suppuration. A great advantage is that its action can be dosed. Experience must show whether or not it acts advantageously upon the ulcerous processes of the cornea.

Iodoform in Ophthalmology. Arch. f. Ophth., vol. xxviii., p. 214.

Deutschmann uses iodoform in solid form, as a powder and as a salve, and saw injuries of the cornea heal well after dusting it into the eye. It also acted beneficially in operative wounds. It failed in ordinary conjunctival catarrh, blennorrhœic affections, and granular conjunctivitis, but proved very effective in the serpent ulcer of Sémisch.

Bad Results of Dusting Calomel into the Eye. Arch. f. Augenheilk., vol. xi., p. 400.

Hotz reports a case in which calomel was dusted into an eye affected with recent rheumatic iritis, producing severe chemosis of the conjunctiva, and cauterizing it where it came in contact with it.

A Case of Acute Conjunctivitis, Caused by the Electric Light. The Lancet, No. 8.

Rockliffe observed lachrymation, photophobia, pain, and swelling of the lids in a workman whose eye had been exposed to an electric light 3,000-candle power. All of these symptoms developed in the course of fifteen minutes.

De la Xérophthalmie Parenchymateuse et de son Traitement par la Transplantation de la Conjonctive du Lapin. Rec. d'Ophthal., April, 1882.

Galezowski mentions a case of xerosis of the conjunctiva, in which both lower lids were united throughout their whole extent to the conjunctiva of the globe to within two mm. of the corneal margin. The left lower lid was detached, and a conjunctival flap transplanted from a rabbit. The result was satisfactory.

Note sur l'Emploi de l'Acide Borique dans les Affections Externes de l'Œil. Ann. d'Ocul., vol. lxxxvii., May, June, 1882, p. 221.

Stocquart reports three cases of blepharitis ciliaris, seven of conjunctival catarrh, fourteen of phlyctenular, and two of purulent conjunctivitis, all of which were successfully treated with preparations of boracic acid.

On the Knowledge of Pterygium. Mitth. a. d. Konigl. Univ.-augenlinik zu München., vol. i., p. 247.

Harder anatomically examined two cases of pterygium. They showed the development of this anomaly, and furnished the anatomical substratum for Arlt's theory that pterygium is due to the superposition of the swollen conjunctiva over a fresh, but healing erosion of the cornea. The loss of the epithelium of the cornea is a *conditio sine qua non*, as is proven by the condition of the fibrillar connective band between the lacunæ. The advance of the pterygium toward the centre of the cornea is not merely a passive one, as proliferation of the substance filling the corneal defect takes place.

Circumscribed Hypertrophy of the Conjunctiva ("Vernal Catarrh"). These Archives, vol. x., p. 414. Arch. f. Augenheilk., vol. xi., p. 391.

Burnett (3) discusses vernal catarrh. It attacks especially children, and consists of a grayish-yellow nodular swelling of the conjunctiva with a well-defined edge toward the cornea: the

nodules may appear singly, or they may surround the whole limbus of the cornea. The remainder of the conjunctiva of the globe is thickened, and in whites of a yellowish-red, in negroes of a brownish color. Papillary excrescences of the tarsal part of the conjunctiva are also always found.

Epithelioma of the Conjunctiva. Ophth. Rev., vol. i. No. 9, 1882, p. 245.

Griffith saw a grayish tumor which occupied the upper part of the conjunctiva and cornea. The eye was enucleated, and the tumor found to be an epithelioma extending to the optic nerve.

Keratitis Interstitialis Profunda. The Diseases of the Eye in Childhood, p. 320.

According to Horner, diffuse interstitial keratitis (parenchymatosa, profunda, scrofulosa, syphilitica) occurs especially in children, between the ages of five and sixteen. A grayish opacity spreads over the cornea, advancing from the periphery toward the centre, and becoming more and more dense. As the centre becomes opaque the periphery begins to clear up. As a rule, both eyes become affected, though not simultaneously, but at an interval varying from days to months. The disease always lasts a long time. Even in those cases which end well, slight opacities of the cornea remain behind. The macroscopic changes alone of the cornea necessarily lead to the conclusion of a constitutional origin of the disease. While Mackenzie and Arlt designate just this form as scrofulous keratitis, Hutchinson has shown its connection with hereditary syphilis.

Five Lustra of Ophthalmological Practice, p. 109. Mooren believes that *interstitial keratitis* is almost solely due to syphilis, and occurs in combination with the deformity of the teeth described by Hutchinson, although the latter is sometimes seen in non-syphilitic persons. The disease generally makes its appearance in childhood, though Mooren has also seen it in a number of persons of advanced age.

Di un Singolare Fenomeno Patologico di Circolazione della Cornea. Gaz. de Ospitale, No. 22, March, 1882.

According to an observation of Denti, severe supra-orbital neuralgia and pericorneal injection developed in a person of forty-two suffering from iritis and numerous synechiæ, whenever the eyes were strained by reading or writing; at the same time a blood-red spot the size of a millet seed developed in the corneal tissue, three mm. from its edge; it was completely isolated and separated from the limbus of the conjunctiva by an opaque, but non-vascular portion of the cornea.

After a few minutes' rest, a fine red thread was seen to extend from the spot to the corneal margin, through which the blood seemed to disappear in the course of two minutes, leaving a dark gray opacity. The whole phenomenon could be produced at will. All the symptoms disappeared after energetic anti-syphilitic treatment of eleven days; the neuralgia became less severe; after the first few days a milk-white spot appeared instead of the red, and finally the whole opacity cleared up. The author explains the phenomenon by supposing that blood, and later, white-blood corpuscles were forced into the corneal lacunæ by increased intra-ocular pressure.

A Splinter of Glass Borne Two Years and Three Months in the Cornea of the Left Eye. Klin. Monatsbl. f. A., vol. xx., p. 396.

Magnus removed from the cornea of a lady a splinter of glass two mm. long, which had been lying between the lamellæ for two years and a quarter.

Keratoglobus. The Diseases of the Eye in Childhood, p. 339. Horner describes that form of keratoglobus as pure, whose sharply defined boundary and absolute transparency have been determined by several observers. Later in life it may become important only by a change in the refraction and disposition to cataract. In pellucid keratoglobus the cornea appears hazy, the globe is very hard, the pupil of normal size and almost immovable. Eserine generally causes a temporary disappearance of the opacity. If an eye affected with turbid keratoglobus is left to its fate, the opacity comes and goes at varying intervals. The cornea constantly grows, the whole anterior segment of the globe is pushed forward by the distension of pericorneal scleral zone. At the same time the excavation of the disc due to the increased tension becomes more and more apparent. The whole picture of turbid keratoglobus is that of glaucoma; the whole process may be set down as congenital glaucoma.

Five Lustra of Ophthalmological Practice. Page 114. Mooren found that far more women than men are affected with episcleritis. It is generally due to rheumatism and gout, but sometimes it is a complication of scleroderma, menstrual disturbances, and scrofula.

A Chip of Iron Ten Years in the Aqueous Humor. Klin. Monatsbl. f. A., vol. xx., p. 320. By Landesberg.

Foreign Body in the Anterior Chamber. Cronica Oftalmologica, May, 1883.

Santos Fernandez mentions three cases of foreign bodies in the anterior chamber. In the first

they consisted of three particles of stone; in the second, a chip of iron; and in the third, a particle of molten iron. In the first two cases the foreign bodies were removed by keratotomy combined with iridectomy; in the third, by keratotomy alone.

Archiv. f. Augenheilk., vol. xii., p. 90, Holmes, and Williamson, Lancet, No. xii., *extracted eyelashes from the anterior chamber. In Holmes' case, the eyelash had caused traumatic cataract.*

(To be continued.)

CORRESPONDENCE.

Santonin in Gleet.

EDS. MED. AND SURG. REPORTER:—

In perusing the article in the MEDICAL AND SURGICAL REPORTER of January 5, 1884, entitled "Santonin in Gleet," I would say, although I had very little faith in the remedy when recommended for said disease, I nevertheless ventured to give it a trial in a case of some three months' standing, and must be candid in saying, that outside of the narcotic effect and the disturbance of vision and confusion of colors, it had no effect whatever on the gleet discharge, probably owing to the fact of there having been no lumbri in the alimentary canal (as in the case of Dr. Anderson) to produce through reflex irritation a leucorrhœal discharge, and upon the removal of the cause a cure of the disease.

ANDREW L. WITTKAMP, M. D.

117 Green Street, Philadelphia.

Treatment of Coma.

EDS. MED. AND SURG. REPORTER:—

An account of a case of possible poisoning by chloric ether and a bromide, by Dr. S. M. Ward, of Ellenville, New York, which appeared in the REPORTER, December 22, 1883, was to me an interesting one, on account of the many errors therein expressed, as I conceived, both as to diagnosis and therapeutics. Dr. W. promptly obeyed a summons to the bedside of his patient, Dr. A., who was found lying on his back, with normal temperature, pulse about 40 per minute and irregular, eyes half open and glazed, insensible to touch or light, respiration stertorous—which scene soon closed by death.

The death certificate in Dr. A.'s case was made out apoplexy, though the attending physician demurred. What is apoplexy? or the real pathological state of the cerebral body itself? There may be fatal apoplexy from embolism, or from a thrombosis. One in apparent rude health is suddenly stricken down with an apoplectic seizure, the result of too much blood within the brain, and if there is no effusion, no thrombosis, recovery follows; on the contrary, death ensues. How does alcohol act; what are its physiological and therapeutical effects? Alcohol administered to a person in health, increases the activity of the brain, in fact, stimulates or promotes the function

of every part of the human organism, but is followed by a corresponding degree of depression, and if persisted in continuously, frequently produces fatal cerebellar paralysis. As a therapeutic agent it will restore the healthy function of a brain depressed by fear or anger, and simple collapse from excessive depletion may be quickly removed. The indirect effect of alcohol is a *fac simile* to that of ether; acting as a depressant, heart failure may occur by virtue of its depressing action upon the motor influences of the brain, and the impulse of the heart is impeded, if the integrity of that part of the sensorium, which presides over such influences, is not preserved.

In heart failure, dependent upon its many diseases, *per se* it is unaccompanied by brain trouble, at least never preceded by such grave cerebral disturbances, as recounted in Dr. Ward's case.

Recently a young man came hurriedly to my office, greatly alarmed with feelings of impending death; being employed at the time, I requested the patient to compose himself, and quickly procured an alcoholic stimulant, which he failed to swallow, stating that others had recommended the same, and that it made him worse. Then for the first time I examined him, finding a feeble, thread-like, and irregular pulse, great dyspnoea, countenance pale as death, with no perceptible heart-sound. I was impressed with his imminent danger, for he seemingly could live but a few moments, from heart failure. Administering, instantaneously, a full teaspoonful of tinct. digitalis, patient was sound asleep in half an hour, with a good round pulse and uniform warmth of surface.

Walking down the street early one morning, I discovered a young lawyer (down and drunk) lying prostrate upon the pavement. Every attempt by passers-by had signally failed to arouse him. Apprehending imprisonment or something else might befall the poor fellow, I tendered my services. There was profound stupor, stertorous respiration, pulse about forty and irregular, eyes covered with film, general aspect livid. After pouring cold water upon his head incessantly for half an hour, he got up, called for breakfast, and sauntered off for a restaurant. Many similar cases have obtained as rapid relief under my observation.

A few years ago I was called in consultation with Dr. C. to see Prof. W.'s eight-year-old boy, who had plied himself freely from his father's private bottle. He had been subjected to a varied scientific treatment, with fruitless results. His condition was that of most pronounced coma—stertor, pulse slow, irregular, and becoming feeble, with commencing cyanosis; eyes filmy and insensible to touch. After pouring gallons of cold water assiduously on his head, he was left sitting up in bed.

We obtained in the cases cited above the therapeutic effect of cold water upon a cranium filled to repletion with blood, poisoned and unærated; the water, constringing the arteries and veins, distended to their utmost capacity, propelled the blood forward to its proper destination, thereby re-establishing the healthy function of the brain. The physiological effect of cold water upon the head, or its action on the brain in its normal state, even simply by drops unremittently applied, causes death by its direct sedative influence.

I will conclude with the postulate, that Dr. A.'s death-trouble was apoplectic in its nature; when he had recovered semi-consciousness by the spontaneous emesis acting as a revulsive, alcohol was administered—the remedy of all others most contraindicated—which continued to gorge the oppressed brain with more blood, not only exhausting what little excitability was left, but burnt up the limited supply of oxygen inhaled, that was intended to eliminate the poisonous carbon in the blood. Doubtless extravasation did take place, but the remedy, *par excellence*, that always maintains a healthy tonicity of the vasa vasorum, is *ergot*.

JAS. GUILD, JR., M. D.

Tuskaloosa, Ala.

NEWS AND MISCELLANY.

A Request.

Having been appointed by the Adjunct Montgomery County, Pa., Medical Society to prepare an essay upon "The Use and Abuse of Alcohol as a Medicine," to be read on March 7, I do most respectfully ask all physicians who read this to briefly answer the following questions:

1. When should it be used?
2. How is it most abused?
3. Have any cases of inebriety been produced in your practice through the use of alcohol as a medicine?
4. Is alcohol in your opinion indispensable as a medicine?
5. Is there a substitute for alcohol, and what is it?
6. Is inebriety hereditary?

These are serious questions for us to consider, and I am very anxious to have the opinions of honest practical physicians, so I may be able to treat the subject intelligently.

By complying with the above request you will much oblige

JNO. B. CARRELL,

Jeff. Med. Coll., Class of 1876.

Hatboro, Pa.

The Garfield Hospital.

At a recent meeting of the incorporators, it was announced that the total cost of the property, together with the sums thus far authorized to be expended for improvements, would amount to \$49,500, and that a suit in connection with an estate, until lately pending in Philadelphia, had been decided in such a manner that the hospital had come into possession of the funds at issue. A board of directors was elected, including Dr. Samuel C. Busey, of Washington, and Dr. John S. Billings, of the army.

Micro-photography.

Before a recent meeting of the Academy of Medicine in Ireland, Dr. Dickenson made a communication on the art of photographing microscopic objects, exhibiting a number of specimens produced by himself, and the apparatus used for the purpose. Having reviewed the history of micro-photography, he demonstrated that the dif-

ficulties in its application were now in a great measure removed. His apparatus was of the simplest kind, consisting of three parts—the first an inexpensive magic lantern, illuminated by a triplex petroleum lamp, with the ordinary combination of lenses, and an extra tube, with a small bull's-eye condenser; the second, a microscope, placed horizontally, without the eye-piece; and the third a frame to hold the glass screen for focusing the image, and to receive the sensitized plate when photographing. He then exhibited a series of pictures produced by the apparatus.

American Salt Pork.

We note from an exchange that M. Paul Bert, the politico-physiologist, does not believe in American pork, even when well salted and prepared with good brine, as these processes would not prevent the pork being infested with trichinæ. At a recent meeting of the Chamber of Deputies, he protested against the revocation of the decree of the 18th of February, 1881, which prohibited the importation of American salt pork. The rescinding of the decree, he remarked, might not be considered impolitic, but it was certainly against the interests of the public health, which should not be left to the mercy of provincial maires and private cooks. He therefore proposed that the decree of the Minister of Commerce authorizing the importation of American salt pork should be left in abeyance until the subject had been fully discussed at the Chambers. This proposition was adopted by a large majority.

The Medical Profession in France.

According to a writer in a recent issue of the *Gazette Hebdomadaire de Médecine et de Chirurgie*, the number of practitioners (including physicians and *officers de santé*, but not including midwives) has increased from 14,376 to 14,846 since the last census was taken, in 1876; while the increase of the total population has not been sufficient to prevent the proportion of practitioners from rising from one in every 3,807 to one in every 3,235. It is the doctors that are growing in numbers, the *officers de santé* having actually diminished. The latter constitute a lower grade of practitioners, the final disappearance of which is likely to take place without the need of any legal enactment for the purpose. The midwives are even more numerous, and the writer in question estimates that there could be only eighty confinements annually for each one of them, supposing that the doctors did no midwifery.

Sewage Farming.

We recently noted that the sewage farm in the town of Pullman, Ill., had been conducted very profitably. We now read in the *Lancet*, December 15, 1883, that the sewage farm at Reading (England) has not been profitable during the past year, although at first blush it seemed that it had been; but no allowance had been made for the rent of the land. In sewage farming, as in every other kind of farming, everything depends upon the business qualifications of the management.

Retributive Prohibition.

It is proposed that Congress enact a law that would virtually prohibit the importation of French and German wines. In view of the embargo placed upon the shipments of American pork to those countries, it would seem as though a sense of retribution were at the bottom of this measure. Should it become a law, it would prove a very serious matter to the countries in question, in view of the very large importations of wine into this country.

Disinfection of Rags.

Surgeon-General John B. Hamilton, of the Marine Hospital Service, has made arrangements, through the State Department, for the thorough disinfection of all Egyptian rags stored in Alexandria, and bound for the United States. This disinfection is to be performed before the rags are shipped, and will consist in steaming them, and subjecting them to such other disinfectants as may be found necessary to purify them.

Weston's Walk.

Weston, the pedestrian, has undertaken a great walking task. At the instance of some English temperance societies, he has agreed to walk fifty miles a day for one hundred consecutive days, and to deliver a temperance lecture each day after his walk. He is to use no liquor during the time. At last reports he had accomplished about one-half the allotted task, and was in good condition.

Items.

—The death is announced of M. Carrière, for some years physician to the late Comte de Chambord.

—The bazar recently held in Baltimore for the benefit of the Presbyterian Eye, Ear and Throat Charity Hospital, realized \$6,500—net.

—A photographic studio is now attached to most of the French hospitals, in order to make pictures of patients with various diseases.

—Dr. Chunn told a recent meeting of the Clinical Society of Maryland that he had removed the stem of a lily from the bladder of a woman.

—In the *Cinn. Lan. and Clin.*, December 29, 1883, Dr. N. P. Dandridge reports a case of removal of the right kidney, where death occurred from uncontrollable hemorrhage.

—Prof. Burt G. Wilder, of Cornell University, will deliver the Cartwright lecture for 1884, in New York city, February 2, 4 and 6. The subject will be "Methods of Studying the Brain."

—In the *Gaz. Médicale de Paris*, November 24, a case of aphasia with integrity of the third left frontal convolution, but with damage to the subjacent white matter, is recorded.

—In the *Boston M. and S. Jour.*, January 17, 1884, Dr. C. M. Green reports a case of mammary cancer; operation; subsequent catarrhal pneumonia, with cancer of the lungs and death.

—Said an Irish coroner: "Can you tell us, doctor, if the deceased were awake or asleep at

the moment of his death?" His countryman replied: "It is very difficult to say, but possibly he awoke to find himself dead."

—A new journal of public health has just been issued at Bordeaux under the title of the *Revue Sanitaire*. It is edited by Dr. Alexandre Layet, formerly of the French navy, and also Professor of Hygiene of the Faculty of Medicine. The first number contains an excellent historical account of trichinosis, and a criticism of the English system of free trade in pork and other articles likely to contain the parasite.

QUERIES AND REPLIES.

EDS. MED. AND SURG. REP.—

In "Fothergill's Hand-book of Treatment," in the article "Body Heat, and Fever," I find the following formula, which he says will probably be "the fever mixture of the future:"

"R. Acid hydrobromic,	3j.
Syrup simplicis,	3ij.
Aque,	
6 <i>td</i> quaque hora."	ad. 3j.

I desire to trouble you to interpret for me 6 *td*. I thought I knew the meaning of all the abbreviations and symbols used in medicine, or could find them. But this 6 *td* gets beyond me. I neither know its meaning, nor can I find it in any book to which I have access. If, then, you will take the trouble to inform me, I shall be much obliged.

Athens, Texas.

T. M. M.

Ans.—6 *td* means sixth. As it is still common in England for physicians to write their directions in Latin, we occasionally see 4 *tā*, 6 *tā*, or 8 *tā*, meaning 4th, 6th, 8th.

MARRIAGES.

BARNES—KILGORE.—At the residence of the bride's parents, Mr. and Mrs. J. J. Kilgore, December 19, 1883, by the Rev. J. H. Fly, J. I. Barnes, M. D., of Daly, Texas, and Miss Jennie Kilgore, of Hondo City, Texas.

ARMSTRONG—COOLBAUGH.—At the home of the bride in Wysox, on December 25, 1883, by Rev. Hallock Armstrong, of Aspinwall, Addison Alexander Armstrong, M. D., of Austinville, and Miss Hattie W. Coolbaugh, all of Bradford county, Pa.

BARRETT—BEACH.—At the residence of the bride's parents, on Saturday, December 27, 1883, by the Rev. Samuel W. Duffield and the Rev. H. W. Ballantine, Louis Randolph Barrett and Alice Butler, daughter of James C. Beach, and granddaughter of the late Rev. Elizur Butler, M. D., of the Cherokee Mission, all of Bloomfield, N. J. No cards.

BURLEY—MOOK.—At "Arcadee," Sound Beach, Conn., on Thursday, January 10, 1884, Dr. C. F. Burley, of Stamford, Conn., and Lillie, daughter of Anna and the late Thos. H. Mook, of New York city.

DEATHS.

CORLISS.—At his residence, Colerain avenue, Cincinnati, Ohio, January 3, 1884, Dr. D. G. Corliss, aged fifty-eight years and eleven months.

DU BOIS.—At his residence in New Haven, Conn., on Sunday morning, January 13, 1884, Henry A. Du Bois, M. D., LL. D., formerly of this city, in his seventy-sixth year.

MOORHEAD.—At his late residence, 256 East Thirty-third street, New York city, January 19, 1884, James Moorhead, M. D., a native of County Fermanagh, Ireland, in the fortieth year of his age.

SHAW.—At his residence, Mt. Lookout, in Cincinnati, Ohio, Saturday morning, January 5, 1884, Dr. Robert Shaw.

SMITH.—At Newtown, Pa., January 20, 1884, Elias E. Smith, M. D.

SMITH.—In Guilford, Vt., December 30, Dr. Hiram Smith, aged twenty-eight years and seven months.

A CASE OF SCARLATINA, COMMENCING WITH CONVULSIONS, FOLLOWED BY COMA AND HEMIPLEGIA.

BY JOHN T. WALKER, M. D.,
Of Philadelphia.

Read before the Northern Medical Association of Philadelphia.

On the 17th of May, 1883, about 1 p. m., I was hurriedly summoned to see Katie B., æt. seven years, of healthy parentage, previously enjoying good health, but convalescent from a severe attack of pertussis, whom I found in general convulsions of an epileptiform character, and Dr. Green, a neighboring physician, in attendance, who had been called in the emergency, and whom we requested to remain. I then learned that on the preceding day Kate had complained of a slight sore throat, and was almost deaf, and that the mother had brushed her tonsils with a preparation of tannic acid and glycerine, which I had a few months previously prescribed for her. About noon on the above date she was suddenly seized with violent convulsions, which lasted until six p. m.

Dr. Green had the patient put in a warm mustard bath, and had given freely, per rectum, potassium bromide and asafotida, without controlling or modifying the convulsions.

The thought which naturally first suggested itself was, what was the cause of the convulsions? The child had an attack of scarlatina, two or three years previously, according to the mother's statement, who is an intelligent lady, and who

evidently was not mistaken, from the accurate description she gave me of the case. Were the convulsions idiopathic, symptomatic, or sympathetic was the question. Was it a case of epilepsy, meningitis, congestion of the brain, or rupture of a cerebral vessel, weakened by the previous attack of pertussis, acute Bright's disease, or scarlatina?

In the absence of any rash, which did not appear in the course of the disease, I ventured, however, an opinion of scarlet fever from the sudden onset of the attack with vomiting, the sore throat, which I had not yet seen, the high temperature, viz., 106½ in the rectum, and the prevalence of the disease at this time. The pulse was frequent and feeble, between 180 and 200 beats per minute; there was a cyanotic hue to the lips and eyelids, and the case threatened a speedy and fatal termination.

I now gave per rectum fifteen grs. of chloral hydrate, and as the skin was not acting sufficiently, I ventured giving a half drachm of jaborandi fluid extract, and later, ½ gr. pilocarpine hypodermatically, with the effect of producing powerful diaphoresis, hoping to substitute the action of the skin for the kidneys, should uræmia be the cause of the eclampsia, although I must confess that as it is such a powerful cardiac depressant and dangerous drug, I would be unwilling to use it in any but a severe case.

Ether was now used by inhalation for a long time, with the effect of modifying, but not controlling the convulsions.

Dr. Green suggested rectal injections of iced champagne, which had the effect of reducing the temperature two or three degrees. Still the con-

vulsions continued, cold being applied to the head, and the ether continued.

Dr. McCamy, a friend, having an appointment with me at my house, was now requested to see the case. He kindly attended with us, the case being so serious for a few days, necessitating almost the constant time and attention of one of us.

About six p. m. the convulsions subsided, when coma supervened, from which she could be aroused sufficiently to swallow a small quantity of milk and a little iced champagne. Dilatation of the left pupil was now very marked, with complete motor paralysis of the right side, pointing strongly to a grave lesion of the brain, perhaps a clot on the left side. The arm would drop helplessly by the side when raised, as well as the leg when similarly handled.

The question was now, was the brain lesion the cause or the effect of the convulsion. In this case no doubt the convulsions were caused, partly at least, by the direct action of the specific virus of scarlatina on the cerebro-spinal system, and not solely to uræmia, as urine drawn from the bladder immediately after the convulsions, was free from albumen and heavily laden with the amorphous urates, although albumen appeared later in the urine, prior to desquamation of the cuticle. The next morning, the 18th, the rectal temperature was 103°, evening 104°; respiration 40; pulse 160; heart apparently healthy but weak; throat examined and found the tonsils and pharynx red and swollen, tongue coated, patient unable to speak, mouth drawn to one side when opened, the tongue deviating when an effort was made to protrude it; countenance expressionless.

Milk was given every two or three hours, alternating with chicken broth, which could be swallowed with some difficulty. Although there was great prostration, and under ordinary circumstances alcoholic stimulants would be demanded to prevent heart failure, we forbid the use of them in view of the brain lesion which seemed very grave, and which exhibited the train of phenomena which characterize a case of cerebral apoplexy, viz., apoplectic coma and complete hemiplegia, associated with aphasia.

We proposed treating the case antiphlogistically, and ordered a calomel and compound jalap powder purge, and a mixture of liq. potassii citratis, and spirits of ætheris nitrosi, containing $\frac{1}{4}$ drop dose of tr. veratri viridis every two hours. The nape of the neck was blistered with cantharidal collodion. Free evacuation of the bowels followed, the stools being liquid and offensive.

Patient can now say Yes with difficulty, without comprehending its significance, says it entirely automatically; countenance still stupid.

19th. Rectal temperature 102°; respiration 30; pulse 120; patient improving slightly. Potassium iodide 2 grains, and potassium bromide 4 grains, now given every four hours to favor absorption of the effusion; five doses were given in the twenty-four hours, the child receiving careful attention night and day by the devoted parents. The entire body was sponged twice daily, with whisky and warm water. The kidneys were acting nicely, but the character of the urine not known at this time, being passed freely but involuntarily, and not deeming it necessary or prudent to annoy the little patient with the catheter.

20th. Rectal temperature, 100; respiration, 20; pulse, 100-110, still improving; passed a fair night, appetite recovering, drinks milk and beef tea with a relish, and when requested to hand something to her different friends, can tell the right one to whom to give it. The pupil is still dilated, but gradually regaining the normal size. Potassium iodide and bromide continued, also the daily sponging.

21st. Rectal temperature, 100; respiration, 20; pulse, 100-112, varying a little during the day, the morning record being given. Can still only say Yes, but looks more intelligent, and seems to understand pretty well what is spoken without the ability to speak.

22d. Rectal temperature, 99; respiration 26; pulse 100-110, countenance more intellectual; plays in bed with her picture-books and dolls. The same medicine ordered, with the bromide increased to 6 grs., and in addition the following given to relieve constipation: Calomel and sodium bicarb. āā 3 grs., and 5 grs. pulv. rhei., which was followed by three good stools.

23d. Rectal temperature, 99 $\frac{1}{2}$; respiration, 18-20; pulse, 100-110. The patient seems a little depressed from the purge; the pupil is still dilated slightly. The throat trouble has improved, but a bronchial cough has annoyed the patient for the past few days, being relieved by the free use of Tolu syrup, not wishing to use opiates in any form which might excite the brain, and also cause a diminution in the amount of urine.

24th. Rectal temperature, 99°; respiration, 18; pulse, 100; looks better, but cannot yet speak, with the exception of the one word "yes."

25th. Temperature in the mouth, 98 $\frac{3}{4}$ °; respiration, 18-20; pulse, 100; less bronchial cough, which is daily subsiding; bladder irritable, passing the urine frequently, which now contains

about fifteen per cent. of albumen; is opalescent from the amorphous urates; specific gravity, 1.030, and contains tube-casts in small quantity.

26th. Temperature, normal; respiration, 18; pulse, 92-100; urine contains less albumen; no tube casts discovered with the microscope; some epithelium, and a large quantity of pus corpuscles, probably from the bladder.

27th. Temperature, normal; pulse, 90-100; respiration, 18; urine, 1.032, acid, yellow, and clear; patient passed a restless night, the heart being irregular in action; she seemed somewhat prostrated, and now alcoholic stimulants were cautiously given with good effect.

28th. Urine, neutral; pus corpuscles not discovered, but some tube casts. Patient has a good appetite, and looks cheerful, but there is no change in the paralyzed limbs. Prescribed, in addition to the iodide and bromide of potassium, tinct. digitalis and dilute muriatic acid.

29th. Temperature, normal; general health improving, but a severe ulcer has formed over the tibia, from the free use of mustard during the convulsions; dressed it with morphia, oxide zinc, and cosmoline, which afforded relief and gradually healed it.

30th. Urine yellow and clear; specific gravity, 1.010; temperature, normal; respiration, 20; pulse, 100; dilatation of the left pupil not now appreciable; appetite good, and heart regular.

31st. Two weeks from the commencement of the attack. She can now move the arm and leg, the leg better than the arm. The urine contains no casts; no pus, but renal epithelium; sp. gr., 1.020. Desquamation is commencing on the chest, and the face looks a little puffy; same medicine continued.

June 1st. Urine yellow and clear, acid and free from albumen; temperature normal; respiration, 18-20; pulse 100; slept well; appetite good.

June 2d. Magnesium citrate given to keep the bowels soluble.

June 3d. Temperature still normal; urine contains no albumen; the arm and leg about the same; a little pallor caused by the energetic action of the magnesia; the potassium iodide and bromide now stopped, and ferri et quinia citrat. given, alternating with the digitalis and dilute muriatic acid mixture; tongue coated; and lemonade to be given freely, as the kidneys seemed sluggish, the urine being diminished in quantity and also very pale.

June 4th. About 8 ounces of urine passed in the 24 preceding hours; sp. gr., 1.022; acid; patient looks more comfortable.

June 5th. She can speak and count when prompted; can repeat some words plainly and others with difficulty; urine contains epithelium and fragmentary casts; no albumen or only a trace; same medicine continued.

June 6-9. Improving slowly; appetite good; can move the arm and leg a little more; urine free from albumen, density normal; passes larger quantity of it; digitalis mixture now suspended, and 2 grs. potassium iodide in the comp. fl. ext. sarsaparilla given four times daily, also the citrate of iron and quinia; speaks more plainly; can repeat almost everything, and can tell her name, which seems to please her, also her papa's, mamma's, and sister's when requested to name them.

June 10th. Temperature normal; respiration 18; pulse 88; ulcer on the leg healing slowly; dusted it with exsiccated alum, and used the same ointment; general health improving; complains of pain in the arm, shoulder and wrist.

June 12 to 21st. Improving a little every day; urine free from albumen; normal density; increased amount, and no casts discovered.

Potassium bromide again added to the iodide, 2 of iodide and 5 of bromide given three times daily; also $\frac{3}{4}$ grains quiniæ sulphate, with 4 m. tr. ferri chlor. as often. She can now stand alone, but can bear little weight on the paralyzed leg; seems cheerful, and is becoming more intelligent; ordered $\frac{1}{8}$ grain belladonna ext. at bed-time for incontinence of urine with good result, only requiring the use of it two or three times. Faradization of the arm and leg showed electro-muscular contractility and electro-muscular sensibility to be about normal. Desquamation is about completed. Stimulating liniments to be used frequently to the arm and leg were ordered, and from this time on until the 7th of July, the improvement in the use of the leg was marked, when she and the mother went to the mountains, continuing the use of the iron and quinine while away for four or five weeks.

On July the 16th, the urine preserved with chloral hydrate was sent me, and found to be normal, free from albumen or casts.

August 23d. The mother brought her to my office to-day, having returned from the mountains a few days previously. Can walk with ease, but has a slight limp, the toes being a little inverted in walking instead of everted as formerly; cannot use the arm yet; the forearm is flexed on the arm, and the hand drops at the wrist, denoting paralysis of the extensors mainly. Todd considers this condition at a late period in connection with hemiplegia, the result of cicatrization, with the loss of a certain amount of cerebral substance.

Should this unfortunately be the case, her complete recovery could scarcely be possible. With an effort she can straighten the flexed arm and hold it for a moment at a right angle to the body. Her conversational powers are yet very deficient, although there has been a decided improvement. She recognized my little girl, whom she knew before her illness, and whom she called by name, although she had not seen her for over three months.

Ordered the following: Strychnia sulphat., grains $\frac{1}{8}$; quinia sulphat., grains 12; tr. ferri chloridi, 1 fluid drachm, and q. s. syr. lemonis to make 3 fluid ounces. M. $\mathfrak{z}$ j. t. d.

August 31st. Improving generally, but little change in condition of arm.

September 3d. Patient complains of frontal headache, especially after too much exercise, and at times seems chilly, but looks better, and the mother says she uses more words to express herself.

Urine again examined and found to be free from albumen or casts; sp. gr. 1.040, heavily laden with the amorphous urates, readily dissolved by gentle heat; passes urine plentifully, eats well, and sleeps fairly. Can raise the arm better to-day than any day since the attack; the fingers are not so rigid, and the power of extension seems to be gradually returning. Same medicine continued, the quinia being increased to 24 grs. and the iron to a drachm and a half. Stimulating liniments still used freely to the arm.

Commentary.—Such is the brief record of a case of severe scarlatina, usually termed malignant, the diagnosis of which at first seemed somewhat obscure in the absence of the rash, commencing with convulsions, lasting at least six hours, with a high temperature, followed by coma and hemiplegia, sore throat, desquamation of the cuticle extending over a long period, albuminuria, desquamative nephritis, with a slight puffiness of the skin over the joints, and with rheumatic synovitis of a mild character, which frequently accompanies scarlatina.

As this was the most severe attack of the disease for one to survive I have ever seen, I considered the case interesting and worthy of note. Although complete recovery has not taken place, yet as the little patient can walk around and even run, and seems to be constantly improving both mentally and physically, I think the prospect of a good recovery quite encouraging.

—Faith is sometimes personified as a drenched female clinging to a sea-washed rock; but a better personification would be a bald-headed man buying a bottle of patent hair restorer.

COLOTOMY, WITH DEVICE FOR RETAINING FÆCES.

BY T. L. HAZZARD, M. D.,

Of Allegheny City, Pa.

This operation is reported to the medical profession not alone because it will add to the record of successful cases, but also because of the apparatus devised for retaining the alvine discharge. The inefficient methods now in use are so distressing to the patient and a source of such perplexity to the operator, as to be considerable of a barrier in deciding the advisability of an operation. The apparatus here used answers the purpose.

Case.—Mrs. N., æt. 50, married, without issue. Ill health began by constipation, headache, and pains through the lower abdomen, loss of appetite, etc. Constipation increased until no solid matter passed; cathartics and injections were futile. October 15, 1881, Dr. Jos. Dixon saw the case. Digital examination of the rectum showed a nodulated stricture about the sigmoid flexure. The smallest probe would not pass the constriction, solid matter had not passed for two months, and for two weeks no matter whatever. The colon, from the sigmoid flexure to the ileo-cæcal valve, was packed with hardened fæces. There was great pain and constant tenesmus. The skin stained bronze; patient thin and weak. Morphia in gr. ij. doses was required to allay pain. She had been fed entirely upon liquid diet. The operation, as advised by Stephen Smith, was performed by Dr. Dixon without any departure being found necessary. The impacted fæces were removed gradually day by day by means of injections of warm water. The improvement was rapid. She recovered her natural color, was free from pain, and with the exception of a little supuration in the upper border of the wound, no bad symptom appeared. The disturbance of temperature and pulse was trivial. Treatment tonic, with an occasional $\frac{1}{2}$ grain of morphia.

In 14 days she was down stairs, in 3 weeks walked out of the house, and in 6 weeks could easily perform her household duties.

The fault of the instruments for retaining the faecal matter is, that if not solids, then surely juices or gas will escape, and when pads of oakum, cotton, or any absorbing material, are used, they must be frequently changed, or a very unpleasant odor attends the unfortunate person. The appliance constructed by Dr. Dixon so well meets all indications, allowing not even gas to escape, and is withal so comfortable, that he is encouraged (after three years of trial in the above case) to re-

port it, hoping it may prove of benefit to surgeons. The most important part can be made by the surgeon himself, and the rest by any instrument-maker or harness-maker. It is made as follows:

When the wound has entirely healed a plaster cast is made of that part of the side contiguous to and over the artificial anus. When the plaster is dry, make a positive cast. A piece of hard rubber three inches wide and about six inches long is to be heated in warm water, and made to conform to the shape of the cast so that the artificial opening will be at the centre of the plate of rubber. Dr. Dixon had proceeded this far when he found that the ball of his thumb exactly filled the opening made into the gut. He carried a piece of ivory (a broken billiard ball) to the turner and had it turned the exact counterpart of the base of the thumb. This was made flat on one side, and screwed firmly to the hard rubber plate so that it would project into the artificial anus, closing it to the exit of alvine matter, and at the same time keeping the opening patulous. A slot is then made in each end for the attachment of straps which go around the body and fasten with a buckle in front. (See cut No. 1.) The strap

Fig. 1.

crossing the back is broad and padded. It was at first kept from slipping up by bandages crossing between the legs, but this was so inconvenient, besides causing irritation, that elastic ribbons were fastened at points of the appliance, and carried to a leather case around the thigh. (See Fig. 2.) The pelvic bones will, of course, keep it from slipping down.

The advantages of this over other methods are:

Fig. 2.

1. It dispenses entirely with the use of bougies. In this case the opening, after three years, has not contracted in the least.

2. It is cleanly, preventing the escape of solids, fluids, gas, or odor.

3. It is perfectly comfortable.

4. It is inexpensive and easily made.

5. The materials of which it is made (hard rubber and ivory) are innocuous, non-irritating, and not capable of absorbing and retaining discharges.

In this case, the patient can easily evacuate the bowels partly by voluntary effort, partly by pressing the abdomen with her hands. She keeps a little cloth between the pad and the skin. This has an aperture for the ivory plug. She anoints the adjacent skin with zinc ointment occasionally. This is the only care it requires, with the exception of an $\frac{1}{8}$ grain of morphia, to control the bowel when she is out of the house for any length of time, making calls or at church. Recent examination shows the lower bowel atrophied to a cord.

A SUMMARY OF REMEDIES FOR THE RELIEF OF SYMPTOMS IN THE ADVANCED STAGE OF PHTHISIS.*

BY MARY HALLOWELL, M. D.,
Of Hatboro, Pa.

As the cough in phthisis often arises aside from the increased secretion of the larger tubes, from an increased reflex excitability of the mucous membrane, and often more or less bronchial and laryngeal ulceration, it is impossible to remove the cause; it can then only be palliated, which should be done—if it becomes paroxysmal and exhausting—otherwise it should not be interfered with.

*Read before the Adjunct Montgomery County Medical Society.

If associated with dyspnoea, arising from tenacious catarrhal products in the tubes, ammon. carb. is indicated, given as follows:

R. Ammon. carb.,	gr. v.
Vin. picis liq.,	gtt. xv.
Syr. acaciæ,	gtt. xx.
Aq. anisi,	q. s. ad. f. ʒj.
M. Sig.—Take every three hours.	

The syrup of acacia disguises the carbonate of ammonia, and also has a beneficial influence on the mucous membrane.

The syrup of wild cherry may be substituted for the tar when a tonic and sedative is indicated in place of the more stimulating tea. If the expectoration be scanty and the cough spasmodic, troches of morph. and ipecac (containing gr. $\frac{3}{10}$ of morph.), generally affords marvellous results.

Oxalate of cerium is beneficial when violent coughing with free expectoration exists with decided gastric disturbance.

It not only quiets the stomach and lessens expectoration, but also exerts a striking influence in diminishing the severity of the cough.

It does not operate well when expectoration is scanty, and because of its tendency to dry the air passages cannot be continued with advantage longer than a few days at a time.

Inhalations are sometimes serviceable, and with some physicians are the sole remedy employed.

The list of agents which can thus be administered possesses the advantage of medicating the air passages directly, without disordering the stomach in passing through the general circulation, and whose virtues are not to be measured by their merely antiseptic qualities.

Of these we have lime and belladonna (gr. j.— $\frac{3}{4}$ iv.), or if the secretions be fetid, carbolic acid may be added, after the combination used by Dr. Coghill, of London, which is composed of

R. Creasoti,		
Acid carbolic,	āā	ʒj.
Tr. iodid. co.,		f ʒij.
Alcohol,		f ʒ iss.

This diminishes the quantity of expectoration, allays cough, lessens, or entirely destroys, fetor of breath.

It may be administered by an extemporized respirateur, made of a cylindrical box, with a perforated cap, in which is placed the absorbent cotton on which the solution is dropped. To be inhaled once or twice daily 10 to 15 minutes.

In the later stages, when the cough is long-continued and interferes with sleep, acetate of morph. may be given with tr. sanguinarie.

The pains in the chest may be dissipated by counter-irritation in the form of tr. iodine and

croton oil or mustard or belladonna plaster. Sometimes a flannel bandage worn around the waist affords a relief not to be obtained from drugs.

The fever requires special treatment. This symptom will not entirely disappear until the substances which cause it are entirely expelled from the body, and for the purpose of abating it, quinia and digitalis, are the main treatment, but neither should be given continuously on account of their injurious influence on the stomach.

Our main reliance, therefore, should be, diet and rest of body. Food should consist principally of milk, boiled grains, and stewed fruit, with a little bread.

Salicin in doses of gr. xx., two hours before the onset, sometimes acts like a charm.

"The night-sweats," Rousselot says, "are entirely subordinate to the fever, and are an effort of nature to reduce the febrile movement, by a diversion to the stomach." He also maintains that when there exists a considerable rise of temperature, with no nocturnal perspirations, we get a diversion towards the intestinal surface and diarrhoea appears. Hence he concludes that it is not always right to check the sweating, especially when it comes on at the commencement of phthisis and accompanies a rapid evolution, pulmonary tuberculization with high fever and active pulmonary congestion.

That in such a case to attack the perspiration is to attack the effect, and not the cause, and is not likely, therefore, to be attended with success. But when abundant sweating occurs, together with a normal flow of urine and frequent diarrhoea it is necessary to direct our therapeutic efforts to arrest the excessive drain on the system of the remedies to be employed. Sponging the surface with whisky and alum is often beneficial. Tablespoonful of whisky at bed-time and another at period of awakening may be given with advantage. If medicines are to be employed, we have a favorite combination in ext. bellad. gr. $\frac{1}{4}$ in pill-form with oxide of zinc, gr. ij. Give one at bed-time.

Dyspnoea, or air hunger, if caused by lungs being choked up with tenacious catarrhal products may be relieved by ammon. chlor; if caused by an over accumulation of secretion in lungs, by an emetic, like ipecac or turpeth mineral.

When caused by reduced breathing capacity of lungs, inhalations of oxygen must be resorted to.

Hæmoptysis requires rest in bed, cold to chest in form of ice, and the internal administration of ergot, ipecac, acetate of lead and gallic acid. Acetate of lead is objectionable because it is a de-

stroyer of tissue. Ergot is physiologically indicated and is quite as beneficial as any.

Monsell's solution, gtt. v—x., $\frac{3}{4}$ j., aq., is used frequently in inhalation.

For irritable stomach, Fowler's solution, gtt. ss.—j., given three times a day before eating, has given good results, and we have in acid hydrocyn. gtt. j. a generally successful remedy.

For the diarrhœa, if occurring early in the disease and dependent on excess of acidity, as told by tongue, give bismuth or chalk mixture.

If later, and dependent on tubercular ulceration, resort to any of the various astringents. Avoid beef tea, and give rice-water as a drink instead of frequent use of water.

A FATAL CASE OF PYÆMIA, WITH POST-MORTEM EXAMINATION.

BY VIERLING KERSEY, M. D.,
Of Pittsburgh, Pa.

Wm. H. G., single, of previous good health, and a brakeman by occupation, was admitted to the West Pennsylvania Hospital on March 26, 1881,

Shortly before admission he sustained a crush of the middle finger, and a laceration and fracture of the index finger of the right hand, while coupling cars. The middle finger being hopelessly crushed, was amputated by Dr. James McCann, and the head of the respective metacarpal bone removed.

The wounds were then carefully cleansed by carbolyzed water, and a dry dressing applied.

Everything progressed favorably until April 2, six days after admission, when patient complained of some pain about the wound; the stitches were removed, and a small quantity of sero-sanguinolent fluid oozed away. On the following morning patient's temperature was $105\frac{2}{3}^{\circ}$; pulse 124. He complained of pain and stiffness of the muscles at the back of the neck, of headache, and anorexia. Afternoon, he vomited a greenish fluid, and experienced some difficulty in separating the jaws, owing to stiffness of the muscles of mastication.

On the morning of the 5th he had a slight chill, followed by profuse perspiration; his temperature in the evening rose to $106\frac{2}{3}^{\circ}$; at this time he was ordered ten grains of quinia sulphate, to be repeated if the temperature did not decline within three hours. The dose was repeated at the expiration of this time, and no effect upon the temperature was detected by the thermometer.

April 6th. Bowels have not moved for three days. Ordered him to have five grains aa of pulv.

rhei and hydrarg. chloridi mite, with grs. ten of sodium bicarb. Also ordered one three grain pill of sulphate quin. thrice daily. Temperature this evening is $106\frac{2}{3}^{\circ}$.

April 8th. Morning temperature, $104\frac{1}{2}^{\circ}$ The extremity of the index finger is gangrenous, and was clipped away with the scissors. The left wrist is swollen, hot, and painful. Ordered grs. xx. of salicylate of sodium thrice daily.

April 9th. Passed a more comfortable night than at any time since onset of complications. Had free evacuation of bowels to-day, discharges being thin and dark-colored. Temperature, a. m., 104° , pulse 106; 5 p. m., temperature 107° , pulse 112. Cold sponging for fifteen minutes caused temperature to decline one degree.

April 10th. Temperature at 8 a. m., $103\frac{1}{2}^{\circ}$, pulse 105. Was delirious during the night, temperature ranging between 107° and $103\frac{1}{2}^{\circ}$. Eight sponge baths with tepid water were given during the night, and each produced a temporary declination in the temperature. Bowels moved freely, and urine drawn by catheter; Hj . of sodium hyposulphite was ordered every 3 hours. At 10 p. m., temperature $105\frac{1}{2}^{\circ}$, pulse 114. Delirium, diarrhœa, tympanitis, stools thin, dark-colored, and very offensive.

From this time he grew weaker and more delirious, had evacuation of the bowels and bladder in the bed, without asking for a vessel. Troubled sleep was induced for as many as three hours at a time, by large doses of bromide of ammonium and chloral. Temperature varied little, ranging between $106\frac{2}{3}^{\circ}$ and 105° .

Died at 1.50 a. m., April 15th, having been in the hospital twenty days, and having been sick of the complication noted in the foregoing report for the past thirteen days.

Autopsy twelve hours after death.—Liver and spleen enlarged, former weighing $6\frac{1}{2}$ pounds, latter dark and soft, and very friable in texture.

Thoracic Cavity.—Left pleural sac contained about three pints, and the right about two pints of fœtid ichorous pus.

The pleura were roughened, and bridles of lymph passed between the costal and pulmonary surfaces. The lower lobe of the left lung, and the posterior part of the upper lobe, were solidified, and sections sank when placed in water. The heart contained two clots, one in each ventricle. That in the right was an ordinary post-mortem blood-clot. That in the left was softened at the centre, and contained pus of a greenish color. The left wrist contained about two ounces of pus in and about the joint.

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE
PHILADELPHIA HOSPITAL.

BY CHARLES K. MILLS, M. D.,

Neurologist to the Hospital, and Professor of Diseases of
the Mind and Nervous System in the Philadelphia
Polyclinic.

Reported by WILLIAM H. MORRISON, M. D.

**The Treatment of Hysterical Paralysis by Rest,
Massage, and Electricity.**

GENTLEMEN: I propose this morning to give you a lecture on rest, massage, and electricity, in the treatment of hysterical patients. A certain number of cases embraced under the the general head of neurasthenic or hysterical cases and a few other cases not coming under these heads, are best treated by the method known as the rest, massage, and electrical treatment.

Let us first take this patient and see if we can make the diagnosis, for I believe that she would be a suitable subject for this plan of treatment. She has been in this hospital a number of years, and before coming here, she had been to other hospitals. She came under my care in 1877, and at that time she was more helpless than at present. For a time she was in the orthopædic hospital under the care of Dr. Mitchell. While under his care, she regained the use of her limbs, and left the hospital walking. This was in 1875. This power was lost when she came under my charge, but after remaining here for several months, she regained the use of her limbs, and was able to walk to a certain extent. She was then sent to the out-wards, but again relapsed into the condition which she now presents. In other words, you have a history of complete or almost complete paralysis of the lower limbs, with several recoveries and recurrences of the helpless condition. She says that it is two years since she was able to stand alone, that she has no feeling in the limbs, and that the arms are a little numb. She has full control over the bladder and bowels, but has occasional diarrhœa. She does not remember ever having had any spasm. In looking at the patient you see that she is well nourished, and that during these many years she has not failed physically or mentally. The lower limbs are well preserved as far as their general appearance is concerned. The temperature is good. When I ask her to move the limb, you see that she apparently has but little control over the muscles of the leg and foot. Examining the patella reflex, I find that on both sides it is considerably exaggerated.

You have here the few points which will enable us to make the diagnosis. These I will give to you, for it is, of course, a question of great practical importance to determine whether you have a case of curable or of incurable paralysis. The case may present itself as one of paralysis of the lower extremities, or as one of hemiplegia, or as one of paralysis of one arm or leg. Here we shall restrict ourselves solely to this case of presumably hysterical paraplegia. If in a case of this kind, there is a history of the hysterical diathesis or of hysterical manifestations extending

over a number of years, no matter what form they may have taken, the presumption is that the case is not one of true organic trouble. The hysterical condition may have revealed itself by the occurrence of hysteroid spasms, or by aphonia, or, as in this instance, by attacks of paralysis with recovery. This latter fact points strongly to the hysterical nature of the paralysis.

Another important point is the fact that it is rare for cases of true hysterical paraplegia to have any great disorder of the bowels or bladder—any *uncomfortable* disorders of these organs. There is rarely any paralysis, either of the sphincter of the bladder or of the bladder itself; no dribbling is present, such as occurs in paralysis of the sphincter or dribbling from overflow as appears in paralysis of the walls of the bladder. Sometimes, especially if the patient learns that a symptom of this kind is to be expected, she will succeed in having apparent paralysis of the sphincter. Here we have had no history of trouble with the bladder. The same is true of the bowels, except occasional diarrhœa.

When you come to examine the limb, remember that the completeness of the paralysis is no indication of its organic character; indeed, I should say that the absolute completeness of the paralysis with retention of the nutrition of the limb, is rather an indication of the hysterical nature of the trouble. In other words, in most cases of focal myelitis, in tumors of the cord, in the various forms of sclerosis, posterior, disseminated, and lateral sclerosis, and so on, the apparent paralysis is not absolutely complete. If destruction of the lumbar enlargement of the cord has occurred from fracture of the vertebræ, syphilitic tumor, hemorrhage, or any other cause, there will be paralysis almost as complete as in this patient, but in addition to the phenomena which she presents, wasting of the limbs and loss of muscular contractility will also be marked.

Two diseases of the cord give phenomena closely allied to those of hysterical paraplegia. One of these is a focal lesion in the mid-dorsal region. If a patient has a tumor of the membrane of the cord, pressing upon the cord and causing dorsal myelitis, he will present symptoms resembling those of this patient, but in nearly all of these cases, there will be in addition, sooner or later, some involvement of the bladder and bowel, and certain localized phenomena of pain, which are not present here. The second affection giving symptoms allied to those of hysterical paraplegia, is spasmodic tabes or lateral sclerosis. This is a disease in which the lateral columns of the cord are supposed to be sclerosed. Here, again, you have phenomena not present in this case. If the patient is closely examined, a condition of tonic spasm of the muscles of the thigh and other muscles of the limb will be found. These spastic phenomena are bi-lateral. The limbs cannot be flexed as readily as I flex the limbs of this woman. The patella reflex is also more exaggerated usually in this form of paralysis than in hysterical paraplegia. In hysterical cases and in lateral sclerosis the contractility of the muscles to electricity, is preserved. The condition of sensation varies in different cases of hysterical disease. Sometimes, more or less anæsthesia will be found with the paralysis. This patient has varied at different

times as regards this symptom. In spasmodic tabes, there is no loss of sensation. In the case of lesions in the mid-dorsal region, the condition of sensation will depend upon the fact whether the anterior or posterior region of the cord is pressed upon.

What may be called the moral examination, or the moral control which you can exert over a patient is of importance. In hysterical paralysis, it is possible to have the patient walk or stand, if you are strong-willed and know how to use your will; whereas, in organic paralysis, this may be entirely impossible.

How should this patient be treated? No golden road to the cure of hysteria is known, any more than to the acquirement of wealth. Nevertheless, certain methods of treatment have proved more successful than others. Sir James Paget, in explaining the supposed pathology of this disease, remarked, "These patients say, 'I cannot.' It looks as though it were, 'I will not,' but the trouble is 'they cannot will.'" This remark would apply very well to this patient. In this expression you have the theory of the pathology of this disease. Hysteria is not uterine trouble. I think this is the opinion of every one who has to any extent studied nervous diseases. So far as the mere uterine trouble is concerned, it is the accompaniment, or the exciting cause of a special hysterical attack, or may serve to increase its symptoms. The uterine trouble *per se* has no more to do with the production of hysteria than have the various derangements of the stomach, or any other organ. The great point, independent of medicinal, hygienic, and other treatment, is to learn to rouse the will of the hysterical patient. This is a cerebral disease, if it is anything; yet it is not an organic cerebral disease. In hysteria, you very often have the same condition that is produced by hypnotizing or mesmerizing a person. There are patients in this hospital who can be hypnotized, as I have shown in this clinic. They will then be at my beck and call, insensible to pain, and, it may be, incapable of moving for a certain length of time. In this, you have the conditions presented by this patient. What is done in mesmerizing a patient? The only theory that is at all tenable is, that in some way certain regions of the brain are inhibited or restricted from acting. You must call off this restraint in hysteria.

The first thing to be done in the treatment of these cases is to secure the confidence of the patient. If you are certain of the diagnosis, you can assert positively that you can cure her; but it is often impossible to cure such patients at their own homes, where they are surrounded by sympathizing friends. Under these circumstances, it is impossible to carry out the various methods of treatment which should be adopted. One of the first elements of treatment is seclusion and isolation. When a patient of this kind comes from a distance to be treated, the best thing to do is to put her in a private hospital, and, if we can afford it, under the care of two trained nurses. You will not be able at a stroke to order these patients to get up and walk. They are, owing to the position in which they have been so long, often in a bad condition, so far as circulation and nutrition are concerned. Some method of helping the will,

some mode of assisting the moral treatment, which is the main treatment of hysteria, is required. Thus it is that rest and seclusion, with massage and electricity, are useful. In some cases full feeding is to be added. This is especially applicable in neurasthenic cases.

I shall to-day have time to speak only of massage and electricity. In using these agents, the best plan is to use one one day, and the other the next. I believe that these two amount to nearly the same thing. They should be practiced midway between meals.

Let me give some idea as to the way in which massage should be performed. I am of the opinion that massage should nearly always be combined with the Swedish movement cure. These two are not the same. Massage is a process in which you rub, strike, percuss, and knead the muscles of the patient, the patient not resisting or attempting to make any movement. In massage, you begin at the toes, first manipulating one toe, then proceeding to another. Then having finished the toes, you next proceed to the joints of the foot, kneading, rubbing, and stroking the muscles. The muscles of the leg are next manipulated. The whole body can be gone over in this way in the course of from half an hour to an hour.

Having carried this out for a week or two, some form of movement should be combined with the massage. In the Swedish movement cure, one object is to call out the suppressed will of the patient. You see that this is very applicable to cases of hysteria. The cure of cases of this kind is often delayed by using massage alone, which is absolutely passive. There are three kinds of movement in this treatment:

1. Passive movements.
2. Active movements.
3. Duplicated active movements.

A passive movement is a movement which is performed on the patient, and is really what is done in most cases by the masseur.

A single active movement is one performed by the patient. Thus, if he kicks, that is a single active movement.

The duplicated active movement is the one which we should perform, or attempt to perform, in connection with massage in hysterical patients.

By this term is meant a movement in which both the patient and operator take part. The operator performs a movement on the patient, which the latter resists, and again the patient tries to perform a movement, which the operator resists. The very substance of this is to call out that which is at the root of hysteria—the want of will power. For instance, you take a foot which, after rubbing, kneading, and so on, you try to flex, at the same time telling the patient to resist you. Then you extend the foot, and the patient again tries to prevent the movement. The other joints of the body are treated in the same way. This is an insinuating, coaxing treatment, and one which will enable you to gain control of the patient in spite of her. As the patient exerts her power, you should yield and allow the part to be moved. The skillful operator knows how much to yield and how much to hold. You see the vital importance of this treatment to substitute massage and the electrical

treatment; by the latter, nutrition and the circulation of the skin, and deeper parts are improved, while by the first you do that which is at the bottom of all successful treatment—you hitch the patient's will to the patient's muscles.

With the plan of treatment already described, electricity should be combined, using it on alternate days. The method of electricity is very simple. The objects to be attained by the use of electricity are the same as in the use of massage and duplicated active movements: in the first place, the improvement of the circulation and of the condition of the muscles, and in the second place, making the patient use the muscles. The Faradic battery should be used in these cases, and the patient should be in a relaxed condition, preferably in bed. There is a method of electrical treatment introduced some years ago by Beard and Rockwell, which is known as general faradization, and is sometimes applied in the office. It can be used in cases of this kind where the patient is not confined to bed. In this method, the patient is placed in a chair, with his feet on a large plate covered with chamois skin; the operator then takes hold of the patient's hand and the other electrode is passed over the muscles of the neck, back, trunk, and extremities. When the patient is in bed, as in the regular rest treatment, this method has to be modified, and then the best treatment is by direct muscular faradization. In this method two sponge electrodes are employed. The sponges are moistened so that the current may pass through the skin and reach the muscles. Both electrodes are taken in one hand, the handle of one being between the first and second fingers, while the handle of the other is between the third and fourth fingers. In this way, the distance between the points of application can be readily altered. The current is then applied to the muscles, beginning with those of the feet, picking out each muscle; then passing up the limb, applying the current to each muscle. You should always remember to relax the muscle before passing the current through it. The whole body can be gone over in this way in the course of half an hour.

It is astonishing to see how cases of many years' standing will improve under treatment of this kind systematically carried out. During the first week, you should not attempt too much; but after a couple of weeks, the patient may begin to sit up and use the limbs in a sitting position. In some cases all this can be done, as it were, in the twinkling of an eye. Some marvellous cures are accomplished in such cases as this. In the majority of cases, you will have to carry out a treatment of this kind to accomplish a permanent cure, and it can be done in every case if you understand the patient. I come back to the point at which I started—the first thing is the diagnosis. Having once made the diagnosis, you can promise an absolute cure. This assurance will often aid in bringing about recovery.

—Holmes says: "Diagnosis has reached a wonderful degree of accuracy; prognosis has become a terrible kind of second sight which is not always handled carefully enough; treatment gains a little with every decade."

MEDICAL SOCIETIES.

NEW YORK NEUROLOGICAL SOCIETY.

Note on the Use of the Menthol Cone as an Anodyne.

Stated meeting, January 8, 1884, Dr. William J. Morton, President, in the chair.

Dr. E. C. Wendt showed a little contrivance, called by the Germans "migräno stift," and explained the method of its application and uses. It consisted of a piece of menthol moulded into a conical shape and secured in a little wooden box, closed by a cover to prevent evaporation, soiling, and breaking. It seemed to be very little known here, although it was much used abroad, especially for sick-headache.

His attention had first been directed to the anodyne properties of menthol by a short notice, published in the *Medical Record*, of April 28, 1883, by Dr. Carmann.

That gentleman had recommended an alcoholic solution of menthol (3 i. to 5 ss. alcohol) to be painted over the affected parts. Dr. Wendt had since that time often used this solution, and found it a rather reliable anodyne.

Its pain-relieving action was restricted, however, to the slighter ailments, especially those of a neuralgic character. Since his acquaintance with the solid menthol-cone, he had frequently substituted the direct application of menthol by means of the latter, for the solution formerly employed. He would admit that the only advantage which the solid cone or pencil had over the solution consisted in the greater simplicity of its application, its ready portability, and the fact that its vapor was not apt to irritate the eyes of susceptible patients. He had repeatedly heard complaints in that direction from ladies, regarding the solution, which was obviated by using the cone.

In this country menthol had not yet received that amount of recognition from the profession, to which its pain-obtaining properties would seem to entitle it. In fact, little seemed to be known about it, and for this reason, Dr. Wendt thought it might not be amiss to quote a descriptive notice which had appeared in the *Midland Medical Miscellany*, of October, 1883.

"Menthol, or menthylic alcohol, $C_{10}H_{20}O$, is a crystalline substance, deposited from the oil of peppermint, prepared in China and Japan from *mentha arvensis* var. *piperascens* and *glabrata*."

It formed the chief ingredient of a much-valued remedy for neuralgia before its nature or source was generally known. Under the name of Po, ho, yo, or *Gouttes Japonaises*, it has been sold in small bottles, labelled with Chinese characters.

It is a white crystalline steareptene, melting when pure at 97° Fahrenheit, and is obtained by the Japanese from the oil of peppermint, by submitting it to freezing several times in succession until no more menthol crystallizes out.

It is also said to be contained in the American and English oils of peppermint, but probably in small quantities only. It is somewhat surprising that the Japanese peppermint plant, which is grown in England as a curiosity, has not been cultivated in that country as a source of the drug,

the supply of menthol being uncertain, the demand great, and the price in consequence occasionally very high.

Menthol is said to be sometimes adulterated with crystals of Epsom salts, to which it bears a great resemblance. These being insoluble in alcohol or chloroform, in which fluid menthol is freely soluble, can easily be detected. Samples of fine crystals sometimes contain some essential oil, adhering to them, a fact which must be taken into consideration, when the menthol is made into cones or pencils.

Menthol is but slightly soluble in water, although imparting a strong odor and taste to that liquid, and is soluble in aqueous alkalies. It is soluble in fixed and volatile oils and in ether.

Although Dr. Wendt's experience with menthol had not yet been a very extended one, it had nevertheless been sufficient to convince him of the utility of the drug, in a rather large class of cases. Thus, as already stated, he had found it a pleasant and reliable anodyne in all the lesser neuralgias, and especially in those so frequently occurring about the face. But it was also serviceable in many painful affections, due to inflammatory processes. For example, in the cervical adenitis so often accompanying sore throat, and in numerous other affections where pain was a prominent symptom, menthol might be used to advantage. With regard to its topical action it was similar to that of aconite, over which it had the advantage of not being poisonous.

Dr. Wendt remembered one rather striking case of quite severe supra-orbital neuralgia, which refused to yield to the oleate of aconitia, but was much benefited by the menthol. But on the whole, in violent attacks, he had found it almost useless. In typical migraine for instance, where the pain was at all severe, and in all deep-seated aches, of more than very moderate intensity, it had no appreciable effect, except perhaps the indirect psychical action of distracting the sufferer's attention.

In the discussion which followed these remarks, Dr. Roberts asked Dr. Wendt if he had tried the prolonged application of menthol.

Dr. Wendt said that he had in some cases of hemicrania, though without decided benefit. Nevertheless, the patients experienced a pleasant sensation of coolness of the surface followed by a feeling of agreeable warmth.

Dr. Morton desired to ask Dr. Wendt, in what sense he used the word anodyne. Dr. Wendt said in the usual one, of affording relief from pain by blunting sensibility.

Dr. Morton thought that menthol probably acted more after the manner of counter-irritants, by insuring relief in a reflex rather than directly local way. Mustard was a typical peripheral nerve-irritant, and it seemed to him that the action of menthol could be best explained on the same principle, of procuring peripheral nerve-impressions in a reflex way.

Dr. Morton continued that his attention had been first called to the menthol-cone by Dr. Wendt. He chanced to be at the latter's office one day, when suffering from a headache. A few strokes of the menthol gave him at once a sense of relief. He felt the effects of the peppermint to

be as gratefully cooling as the application, say of cold metal. In brachial neuralgia, as well as in sciatica he had been pleased with the good effects of menthol. He thought the drug was deserving of further trials.

Dr. Ralph L. Parsons then read a paper on

Detention in Asylums.

The reader spoke first of the question: Whether sane persons were not often improperly or unjustly detained in Asylums for the insane; and secondly, whether many uncured and incurable patients who were now methodically detained in asylums might not advantageously be returned to their relatives, or placed in the care of private families under State supervision?

It was assumed in the first instance that the detention of patients after recovery had taken place, for a longer time than might be required, was quite possible, and even probable in some instances. But he claimed that such detentions were not usually of serious import to the patient; that on the other hand, too early discharge might be more injurious. It was also admitted that maliciously unjustifiable detentions were quite possible, as any other sort of injustice is possible on the part of persons holding positions of power and responsibility. But reasons were urged by Dr. Parsons, in support of the belief that such malicious detentions were at least very rare; that sentiments of honor and professional pride were strong deterrents, to say nothing of the great danger of detection in the commission of the wrong, and the ease with which patients who were decidedly insane obtained their enlodgment through the intervention of the courts.

Cogent reasons were given why various classes of convalescents ought to remain under asylum care for a period of time after they appeared to be well; as, for instance, when they would be immediately subjected to the exciting cause of their insanity on their return; when the progress toward convalescence had been characterized by relapses, or when dangerous delusions had been entertained and had faded away so gradually that there were difficulties in judging whether they had passed away entirely.

But on the other hand, the discharge of certain uncured curables before they were well was advised, as when after making a certain degree of improvement, this improvement stopped and the patient second to retrograde. It might be safe and highly advisable to discharge some of these patients before they were well.

The major part of the paper was devoted, however, to an advocacy of the discharge from the asylum of harmless incurables, and their return to the care of their friends, or placing them with ordinary families as boarders, and in some sort as members of the families. It was claimed by the reader that however comfortable and happy such patients may appear to be in large asylums, there are many causes of annoyance and discomfort that would not be experienced in ordinary family life; that notwithstanding the fine buildings they occupy, and their freedom from care, they are still prisoners, and exposed to many disagreeable associations and associates.

Quotations were made from Dr. Bucknill and from Dr. Baudsley, strongly supporting these views.

The question was then considered, what classes of incurables might safely and with benefit, be released from asylum restraints. Since in the case of a great majority of such patients, a moderate cost of maintenance would be essential, those only would be adopted who were quiet and would require no especial attendance or supervision. Habits of industry would be favorable.

Whether such patients would do better with their relatives, or with strangers, would depend on the circumstances of the family, the state of health, the surroundings, the feelings or notions of the patients, etc. It would be found, however, that many patients who would not do well with their own kindred, would be happy, contented, and useful with congenial strangers. It would be impossible for the patient to resume his former position and influence in his own family, and hence he would be subjected to irritating restrictions and annoyances there.

As a preliminary measure, a system of legalized furloughs was advocated, to the end that at first the patient might still be under legal restrictions and easily returned to the asylum, if the trial at large should prove a failure.

Properly constituted authorities should make the selection of patients for the trial, with the assistance and under the advice of the asylum superintendent.

The families in which the patients should be placed should be selected with great care. While at first there might be found very few suitable families who would assume the charge, it was thought that, when a beginning had been made, plenty of suitable homes would be offered. Reference was made to the multitude of respectable and responsible families who take summer boarders for a moderate compensation, and the probability that some of these families would prefer one or two permanent patient boarders, to a number of sane boarders for a short season during the busiest portion of the year. A suitable system of visitation and of reports was advocated. The paper closed with the following summary of conclusions, to wit:

1. That, inasmuch as many recoveries take place in asylums for the insane, it is to be expected that some convalescent patients may at any time be found in the wards.

2. That while possibly now and then a convalescent patient may be detained on probation an unnecessary period of time, such cases are not of frequent occurrence, nor important in their consequences when they happen; and that when they do occur the detention is very rarely indeed through criminal intent.

3. That many harmless incurables are unnecessarily detained in asylums for the insane; that these incurables would be happier in the enjoyment of ordinary family life and associations, and that systematic efforts should be made to secure their enrolment and their establishment under family care.

4. That under certain circumstances curable patients should be removed from asylums, restraints, and associations while yet uncured.

Owing to the lateness of the hour, the discussion upon Dr. Parsons' paper was postponed until the next meeting of the society.

MEETING OF THE ADJUNCT MONTGOMERY COUNTY, PA., MEDICAL SOCIETY.

BY DR. JNO. B. CARRELL,

Of Hatboro, Pa.

For the MEDICAL AND SURGICAL REPORTER.

The Society met at the office of the President, Dr. Jno. Paxton, in Jenkintown, on January 11th. The President occupied the chair.

At the last meeting Dr. Coltman, Sr., reported one of his cases in practice in which the antipyretic power of quinine in typhoid fever, etc., was clearly shown. The report of the case can be found in this journal, on page 586, issue of November 24, 1883. The editor of an eclectic journal, styled the *Medical Investigator*, published at Greenfield, Ind., after giving a few of the less important points of the case taken from the REPORTER, says: "Had the case been treated according to the doctrines of his school a recovery would have been the result."

It speaks badly for a man when he must resort to defamation to keep before the public. The Society considers the article of not sufficient importance to merit a reply. It is merely mentioned so that conscientious physicians can read the article and judge of its merits or demerits.

After the usual routine of business, Dr. Mary P. Hallowell read an article on the treatment of phthisis, in which she has collected many good points. (See page 165.) The subject was discussed by the members, and many cases in practice cited to show the utility of the different methods of treatment. The stimulant plan of treatment was fully endorsed. Dr. Cooper uses with great benefit in night-sweats a drink of strong sage tea, and to relieve the local pains, a liniment made of equal parts of alcohol, tinct. camphor, and aque ammon. To relieve the dryness of the throat produced by belladonna, Dr. Carrell combines with it small doses of ipecac, and for the tough tenacious mucus which is difficult for the patient to raise he uses chlorate of potash by steam atomization.

The responsibility of the medical profession in the use of alcoholic liquor was discussed, and Dr. Carrell appointed to read an original essay at the next meeting on its "Use and Abuse as a Medicine."

Dr. Coltman, Sr., read a selected article from the *Southern Practitioner* on "Is Ipecac a Nerve Stimulant?" by Dr. J. H. Green, of Okalona, Mississippi.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Thursday evening, January 10, 1884, the President, Dr. Tyson, in the chair.

Osteo-Myelitis of Tibia.

Exhibited by Dr. C. M. Wilson.

George L., æt. 42, was admitted into the surgical ward of the Pennsylvania Hospital, November 26, 1883. Sixteen days previously he had been knocked down on shipboard, and had sustained a wedge-shaped fracture of the tibia, and an oblique fracture of the fibula of the right leg about the middle. When admitted the fragments were in malposition and partially united. There was considerable deformity, the lower fragment of the tibia being tilted up and overlapping the upper

fragment. By appropriate treatment the fracture was retained in fairly good position, and the case was progressing favorably until the afternoon of December 26, just one month after admission, when he had a severe chill, followed by a temperature of $103\frac{1}{2}^{\circ}$ Fah. He complained of violent pain in left shoulder-joint. He was treated with salicylate of sodium. Next morning his temperature was $102\frac{1}{2}^{\circ}$ F., with intense pain in both shoulders and elbows. The same anti-rheumatic treatment was continued, under the supposition that the case was one of acute articular rheumatism, the man having been exposed to a draught. The afternoon of second day he had a severe chill, with an evening temperature of $104\frac{3}{4}^{\circ}$ F., and a pre-systolic mitral murmur was detected. Dr. Wilson now considered the case to be one of pyæmia, and gave massive doses of quinia, stimuli, and digitalis. Man steadily grew worse, and died of exhaustion on the morning of December 30.

Post-mortem twenty-six hours after death. Rigor mortis marked; body well nourished; posterior portion of body much discolored; extensive ecchymoses over arms and shoulders; smaller patches over abdomen and chest; one and a half ounce of clear serum in the pericardial sac, with many ecchymoses over the surface of the heart; both sides of heart relaxed and partially filled with post-mortem clots; the valves on right side appeared normal; the aortic valves were incompetent, and their free borders were roughened by recent vegetation; there was also some slight thickening and contraction; the mitral valves showed old thickening as well as signs of recent inflammation; the endocardium of the left ventricle showed numerous spots of ecchymoses; the heart weighed sixteen ounces, and its tissue was a good deal softened; spleen normal; left kidney weighed seven ounces, was somewhat swollen, and its tissues were slightly flabby; the capsule was thickened and somewhat adherent; the organ was congested and somewhat swollen; right kidney weighed six ounces, and presented the same appearance as the left; liver was large, swollen, and marked by the ribs; its surface was mottled with rounded yellowish patches, surrounded by dark-red areolar; section showed it to be markedly congested; its weight was four pounds four ounces; lungs much congested; the base of the left being anteriorly bound down by old adhesions. The brain was not examined. Examination of the fracture showed it to be ununited, and there was no callus detectable. The periosteum tore easily. On section the medulla of the cavity of the tibia showed marked evidences of inflammation. There was a puffy septum of granulating tissue between the ends of the fragments. Above there was evidence of extravasated blood, and two and a half inches above the line of fracture there was a small circumscribed medullary abscess. The medullary cavity was inflamed and streaked with red lines. Through the kindness of Prof. Brinton and Dr. Longstreth, Dr. Wilson was enabled to show several pictures illustrative of osteomyelitis. This is the only case of death from a simple fracture recorded at the Pennsylvania Hospital. This disease must be a very rare sequel of simple fracture. It is not necessarily a fatal disease, as the inflammation may become circumscribed, a depot of pus formed, and the destructive processes

end there, or a portion or the whole of a bone may die or be removed. It is easy to see how a virulent inflammation going on to suppuration with no vent to the pus, as in this specimen, could readily give rise to septic poisoning. I am indebted to the courtesy of Dr. Longstreth both for the specimen and assistance in its preparation.

Dr. Tyson said that he had seen many cases of osteomyelitis from gun-shot injuries during the late war, but he could not recall a case where the medullary canal was encroached upon by a condensing osteitis, as in this specimen.

Dr. Nancrede related a case of fatal septic trouble following a simple fracture of the thigh, where the starting-point seemed to him to have been a superficial ulceration of the spine, produced by the adhesive plaster. Possibly section of the bone might have revealed an osteomyelitis, but as the fracture was firmly united, he thought that the skin abrasion was the starting-point, and related two cases of pyæmia produced by equally trivial causes.

Dr. Longstreth related a case seen by him when a resident physician at the Pennsylvania Hospital. The patient had a fracture of the thigh of three weeks' standing, and was apparently doing well, when chills, sweats, lung consolidation, etc., ushered in a fatal attack of pyæmia. A post-mortem revealed osteomyelitis and general pyæmic manifestations. A possible explanation of Dr. Wilson's case was that the man had been on board ship for three weeks after his injury, where the treatment must have been of the crudest description.

Dr. Eskridge called attention to the endocardial trouble found in septic disease, which he had been taught as a student to consider was of an ulcerative form, and of fatal prognostic import. He had, however, seen two cases which presented all the symptoms of ulcerative endocarditis, but which had recovered, while in two others, with a similar clinical history, post-mortem examination revealed only a simple non-ulcerative endocarditis.

Dr. Shakspeare asked whether this condensing osteitis might not have been due to a previous syphilitic trouble.

The Dread of Number Thirteen.

The hold that superstition has on human nature is well illustrated in the following: "*Galigan's Messenger* says the superstitious dread of the French for the number thirteen is well known; and a curious manifestation of that aversion has just been made before the Paris Municipal Council on a question put by M. de Lanessan to the Director of Works. The latter said that applications were being continually received, from owners of houses bearing the No. 13, to have the number changed; the request being supported by the tenants. In the case of a street in which numbers follow and exceed thirteen, the demand is not admitted, as it would necessitate a modification of all the succeeding numbers; but, where the No. 13 was the end of the series, the city, by a sort of toleration, allowed the last house to be numbered 11*bis*; which was the case of the last house at the extremity of the Boulevard du Palais, which gave rise to the question."

EDITORIAL DEPARTMENT.

PERISCOPE.

Catheter Fever.

Sir Andrew Clark read a very interesting paper on this subject before the Medical Society of London (*Lancet* December 22, 1883), which thus concludes:

First, that about middle life in men perfectly healthy, or with no discoverable evidence of disease, except perhaps, and even that not always, a low density of urine, the commencement of the habitual use of the catheter is sometimes followed by fever of the remittent type, which often ends in death, and that for the fatal issue in such cases no adequate structural explanation can be found. Secondly, that it is important that such a fever, arising in the midst of apparent health from such a seemingly small cause, and leading so often (as it certainly does) to a fatal issue, should be well and widely known, lest death should take the friends of the patient by surprise, and arrangements necessary to the welfare of a family should be left unmade. Thirdly, that although it is well known that in persons affected with renal disease, or with chronic gout, or with grave disorders of the general health, the commencement of habitual catheterism is attended with peril to life from secondary fever, the fact that this fever may arise in what seems to be good health, and without the mediation of any visible structural lesion, issue in death, is not well known—or at least well known only to a few—and has, I repeat, no adequate place in English surgical literature or in the English surgical teaching of this time. Of course, this knowledge will be found, as I have in a very imperfect way shown you, in special monographs and papers, but those are the luxuries of the few, and for the most part the luxuries of specialists who work in that direction; but such knowledge should be, as I think, fully imported into our common textbooks, and so made accessible to the whole body of the profession. Fourthly, that this fever is neither distinctly uræmic nor distinctly pyæmic; that although, having some of the characters of each, it has all the necessary characters of neither; that probably it begins in the nervous system; that probably the disturbance of the nervous system reacts in the first instance upon the general metabolism of the body, and in the second instance upon the secretory organs, beginning with the kidney; that the effect upon the kidney may consist either in structural alterations of the kidney, invisible by the aid of our finest instruments of research, or (as seems to me much more probable) in alteration of the constitution of the blood, that dynamic condition of its constituents in the renal vessels essential to the elaborative action of the secretory cells thereof; and lastly, that the concurrence of these conditions may, and often is, enforced by septic reabsorption into the blood. Fifthly, that a more complete knowledge of this variety of fever, and of the conditions of its origin, maintenance, and in-

crease may, at least we may hope, lead to a material diminution of its mortality; and that even now, by treating in a serious manner entrance upon catheter life by taking the precautions set forth by Sir Henry Thompson, by great temperance in the use of foods and stimulants, by rest, warmth, and by other general means, upon which I shall not now dwell, such mortality, I repeat, may be possibly considerably diminished.

Of these propositions, the one at present most open to attack is the fourth, wherein it is asserted that this fever is not distinctive and exclusively uræmic. For in these days it has come to pass that almost every writer of distinction adheres to the view of the uræmic origin and nature of catheter fever, or of the thing known under that and other names, and I am, as it were, left by myself very imperfectly armed to oppose it. I oppose it. I ground my opposition to the exclusively uræmic theory upon the fact that the phenomena of catheter fever, not as they exist at a particular moment, but in their assemblage and in their progress together, are different from those of the ordinarily recognized uræmia. The duration is at once longer and shorter—longer than that of the acute uræmia, and wanting its headache, its perversions of sensation, its changes in the urine, its convulsions, its profound coma; shorter than that of chronic uræmia, wanting its neuralgias, its recurring headaches, its defects of sight, its fleeting paralyses, its itchings of the skin, its vomiting, its characteristic breath, its attacks of dyspnea and palpitations, its painful nervousness, its low temperature. Furthermore, the urine of the catheter fever of this variety, at least of catheter fever, is always loaded with micro-organisms of various kinds; and although it is deficient in urea and contains more or less albumen, it deposits no tube casts and it is capable of amendment. Lastly, whilst chronic uræmia issues in death, catheter fever may issue, sometimes does not issue, in complete recovery. Sir Henry Thompson may remember that I saw with him a distinguished nobleman, not far from Oxford street, who had to make an entrance upon catheter life, and he very justly and wisely warned the relatives that it was a serious procedure, and that perhaps he might suffer constitutional disturbance after the starting of this mode of life; and it happened that he did suffer this constitutional disturbance. It happened indeed that he had a mild variety of this fever which I am now describing, and that it continued for between a fortnight and three weeks. Eventually, with Sir Henry Thompson's help, he recovered, and I think I may say now, five, six, or seven years afterwards, he is in good health at an advanced age. Except in its long duration, in its occasional rigors of great severity, and its exceptional clearness of mind, the phenomena of what is called endocardial fever resemble more nearly those of the fever which I have called for the moment catheter fever, than any other malady with which I am acquainted.

Two questions of a practical kind arise out of

this study of the history of catheter fever. The first is this: seeing that by almost universal assent the fever originates at least in a disturbance of the nervous system, and seeing furthermore that in the cases accessible to me at least, there is no account of the fever following in cases where narcotics or anæsthetics have been used, may it not be that the fever is capable of being cut short by the administration on entering upon habitual catheterism of narcotic or anæsthetic remedies? I remember that my great master, Syme, in Edinburgh, for a reason which his instincts very often knew better than his understanding, invariably gave his patients whom he had to catheterize frequently a grain or two of opium from the very beginning, and I must also add that he was singularly free from catheter accidents. The second question is this: assuming the presence of the fever, and seeing that the quinine has signally failed in controlling it, what are the drugs to be employed on such occasions? and what is the sort of hygienic management to be followed, especially in respect of food and alcohol, which are so variously used on such occasions, in order that the fever may be brought, if that be possible, to a successful ending?

Such, then, are the main conclusions which I have drawn from my fragmentary studies of this form of catheter fever. I know that they are incomplete; I even fear that they may be inaccurate; but, however this may be, I submit them to your consideration, and I console myself with the reflection that they may call forth the ripened experience of practical surgeons, who, in this matter, furnished with a larger knowledge and a more practiced judgment, may be able not only to correct me where I am in error and to confirm me in any small point where I may have caught the truth, but to supply us with the very sort of knowledge which at this juncture we need and ask.

Antiseptic Dressings.

Dr. Robert F. Weir contributes a lengthy article on this subject to the *N. Y. Med. Jour.*, January 19, 1884, from which we take the following:

In the New York Hospital, prior to an operation, not only are the parts washed with soap and water, but also with a mixture of turpentine and alcohol, two ounces to the pint, both as a solvent for greasy matter and likewise as a penetrating antiseptic—turpentine being a germicide even in so weak a solution as one part to seventy-five thousand.

The sponges in our hospital, as in Germany, after proper cleansing, are kept in an antiseptic solution for a week before they are again used. To carry out this plan we have, as can be observed, on a shelf in the amphitheatre, a row of glass jars, seven in number, representing the days of the week. The sponges are, in the first place, prepared in the following manner: After getting rid of the sand by shaking and beating them, they are thoroughly washed in warm—not hot—water, for if hot water is used it deteriorates the quality of the sponge substance and tends to fix the dirt within its meshes. This is particularly so if the sponges have already been used at an operation. The sponge is then placed in a 1 to 1,000 solution of permanganate of potash for

twenty-four hours. If the permanganate is found to be losing its beautiful pink color, a little more may be added. At the end of this time the permanganate of potash is washed out with warm water. The sponges are now bleached by immersion in a solution composed of one part of sulphite of sodium to one hundred parts of water, to which has been added a one-fifth part of a watery solution of hydrochloric or oxalic acid of a strength eight parts to one hundred. They are stirred up with a stick for a few minutes, until they whiten; if left longer, they will become friable. Then they are washed out with water again, and left for some time in running water. The sponges are afterward put into a carbolic-acid solution, 1 to 20, or in a solution of 1 to 1,000 of the bichloride of mercury, and kept there until used. Sponges so prepared, such as we use at this hospital, cost but about one cent and a half each; and at that price they may be thrown away after use at an operation. This is my custom in private practice; at the hospital it is the rule that, if the operation is one upon the rectum, the vagina, or other parts where contamination is likely to take place, the sponges used are afterward destroyed; in amputations and other cleanly operations upon the otherwise healthy subject, the sponges are cleansed for subsequent use. In all abdominal operations new sponges are employed. The sponges that are to be again used are washed thoroughly in running water, and afterward kept for some hours in a weak carbonate-of-soda solution, to dissolve out the fibrin, etc., and then placed in the antiseptic solution as before. Such are the antiseptic dressings used at this hospital in the wounds to which they are applicable; there are certain wounds of the body, as of the mouth, rectum, and elsewhere, in which it is necessary to employ iodoform, which is better adapted to such localities. If you have no other preparation at hand, you can rub the iodoform into the ordinary gauze or simple mosquito-netting, and apply it to the wound. The sticky iodoform gauze is readily made by rubbing iodoform into the ordinary Lister gauze. Iodoform also makes the best application for small lacerated wounds. But remember that more than forty-five grains will give rise to symptoms of poisoning.

Finally, the principle of rest should be carried out thoroughly. No matter how small the operation—as, for instance, the removal of a small tumor from the ankle—the limb is placed in one of the easily-cleaned enameled iron guttered splints of Volkmann's pattern, and held immovable until healing is accomplished or the risk of inflammation has passed away.

Such are the details of the management of wounds and injuries which at the present time seem best to fulfill the conditions demanded by an antiseptic treatment. It is hardly to be expected that the general practitioner will have at his command all the materials here shown. He can, however, have sundry powders of corrosive sublimate, of eight grains each, in his possession, and, when called to a case of injury, can rapidly add a pint of warm water to one of these powders, bathe the wound freely with the solution, dip into it some cheese-cloth, or, what is even better, ordinary absorbent cotton, then squeeze this out as dry as possible, or, if time allows, partially

dry it by exposure to heat, and apply it to the wound. Drainage can always be accomplished with rubber tubing perforated in the ordinary manner, choosing, when possible, the black or red rubber for the purpose. This dressing, duly secured with a bandage dipped in the same solution, will answer for a first application, and permit you to prepare a more elaborate antiseptic appliance if you wish.

After dispassionately reviewing the advantages of antiseptic precautions, he says :

"With such results, I feel that I shall be pardoned for repeating words used on a former occasion, but now employed with a conviction deepened by increased experience, that 'the saving of life which is thus indicated, occurring as it now does, or ought to do over the whole world, should entitle the name of Joseph Lister to outrank in medicine all of his century, not excepting the discoverer of anæsthesia.'"

A New Treatment for Chronic Noises in the Head (Tinnitus Aurium).

Dr. Bernard Roth thus writes in the *Brit. Med. Jour.*, December 15, 1883 :

"In my practice as an orthopædic surgeon, I have, during the last six months, found Dr. Mortimer Granville's 'precise nerve-vibration,' by means of the percuteur, most useful in relieving and curing various neuralgias of the head and back, which are frequently present in cases of lateral curvature of the spine. Holding the opinion that, in some cases, tinnitus aurium is allied to neuralgia, I was induced to try the percuteur in the following case.

"Mrs. S., aged 57, the wife of a professional man, consulted me on October 16, with the following history. She was quite well up to four and a half years ago, when she took scarlet fever, which was followed in a few months by deafness and tinnitus aurium. The patient was never free from the noises, which had become gradually worse till the day of consultation, although the deafness was much less than it used to be. The noises were now so severe that they were felt all over the head, especially at the top of the cranium; and at times the patient was driven quite distracted, and almost out of her mind. She had tried everything during these four years, without even the slightest temporary relief to her distressing symptoms, although she has been treated by leading aurists. The patient described the noises as varying in character, but generally they gave her the impression of iron filings constantly falling. I applied the blunt ivory hammer of the percuteur over the forehead, and then at the top of the head. The vibration was at once very soothing; and in about five minutes more relief was given than the patient had ever received during the whole of the four years. After waiting about ten minutes, the noises, which had not quite disappeared, became worse, but decidedly less violent than before the percuteur was tried. On applying it again, a similar relief was given. Next day, Mrs. S. reported that she was much better till late at night, when the noises became raging again. I reapplied the percuteur on and off for three-quarters of an hour, which gave even more relief than the first day. All noise did not

disappear, but it was so slight that the patient described it as being 'quite a pleasant chink,' and that she would not have noticed it if she had not been thinking about it.

"On October 24, I saw the patient for the seventh and last time. She had experienced so much relief that she decided to buy a percuteur for home use, and she felt it would give her most relief late at night.

"I am aware this is still an incomplete case; but while I am waiting for the patient to report progress, I am anxious that other surgeons more specially engaged in aural practice should try this treatment in similar cases of apparently incurable tinnitus aurium, than which there is scarcely any more distressing affection."

Caffeine.

Dr. Leblond (*La Tribune Med.*, November 18, 1883) thus sums up a series of papers on the physiological and therapeutic properties of this article:

1. Caffeine is an excitant of the nervous and muscular system.

2. It diminishes the frequency of the pulse, increasing the force of the heart-beat and blood-pressure by the vaso-motor constrictors.

3. It lowers the peripheral temperature.

4. It has no influence on the formation of excretion of urea.

Of the poisonous dose:

1. Caffeine exaggerates the excito-motor force of the spinal cord, paralyzes the peripheral sensitive nerves, and diminishes the sensibility of the pneumogastric.

2. It causes a rapid lowering of the blood pressure through paralysis of the vaso-motors.

3. The heart, in cold-blooded animals, beats slower and slower, to be finally stopped in systole; in warm-blooded animals, it becomes quicker at the close and stops in diastole.

4. It produces tetanic contraction of the muscles.

5. It rapidly lowers the temperature.

6. It increases mal-assimilation.

As a therapeutic agent:

1. It is, as a rule, tolerated much better by the system than is digitalis, and by beginning with small doses, there is no fear of the bad effects often produced by the latter.

2. It steadies the heart, increasing its force and slowing its beats.

3. It produces more or less of a diuresis.

4. Not only is it a substitute for digitalis, but it should *always* be administered in serious cases which may result in immediate death, because its action is surer and more prompt than that of digitalis.

5. It is best to administer the caffeine in small broken doses, in potions or subcutaneous injections, and to never begin with a stronger dose than 20 centigrammes, to determine the susceptibility of the patient, then to increase the dose rapidly, if necessary, to from 50 to 75 centigrammes. It is useless to give more than 1. gramme 50.

6. In affections of the heart it should always be administered when, from any cause, the patient's condition requires that the use of digitalis should be stopped or when it is not well tolerated.

7. Caffeine seems to lower the temperature in pyrexia, being useful also in these cases as a heart tonic.

8. It is frequently very beneficial in albuminuria of cardiac or other origin.

9. And finally, in cases of strangulated hernia it seems to act upon the muscular contraction of the intestine.

The Diet in Bright's Disease.

Dr. Charles Purdy thus writes in the *Chicago Med. Jour. and Ex.*, December, 1883; *et passim*:

We would suggest as the diet for the albuminuric patient as follows: In the main it should consist of farinaceous articles, fish, vegetables, and fruits. Meats must be indulged in sparingly; very small quantities of lean meat alone being permissible. Soups should be prohibited; even the conventional beef-tea and beef extracts. Eggs should be excluded from the diet in albuminuria. It has been shown by Lehmann and Stockvis that when the white of an egg is introduced into the circulation, not only does that escape by the kidneys, but a surplus of other albuminoids accompanies it. Senator says the lesson will apply to meat as well as eggs. "Any excess acts in two ways injuriously—by increasing unnecessarily the amount of urea and other waste products in the blood; and also by pouring into the system an overplus of peptones or other albuminous matters, which may simply have to be excreted, and cause irritation in the act." Cheese acts in a similar manner, and should not be used. Vegetables may be used freely, and the only ones to be avoided are the leguminous ones, which are too rich in albumen. Fats may be used as freely as the condition of the stomach will permit. Milk is one of the best articles of diet, but should not be too exclusive, as it does not furnish the elements of diet in a suitable proportion. The stomach should not be overloaded, it being an occasional observation that even in healthy persons albumen appears in the urine after a large meal. Small meals, more frequently repeated than usual, is a good rule to follow in such cases. Great discrimination is necessary in the matter of drinks in Bright's disease. Alcohol in large quantities, especially in concentrated form, is generally believed to be injurious. If alcohol be permitted at all, it must be well diluted, and it is preferable to give it with some alkali or neutral water, as Vichy or Apollinaris water in excess. Alcohol stimulates the interstitial changes in the kidneys if used in quantities, hence the allowance should be very small—not enough to disturb to any extent the general circulation. Claret, sherry, and Marsala are the least objectionable. As to malt liquors, they should, as a rule, be excluded, though it is stated that lighter pale ales or Bavarian beer are nearly free from objectionable qualities.

Salivary Calculi of the Right Sub-Maxillary Gland.

Dr. J. Bradford Cox reports this case in the *Boston M. and S. Jour.*, January 10, 1884:

Mr. J. D., aged fifty-two years, born in Prussia, single, a mechanic, in January, 1879, had an inflammation of the right submaxillary gland, which lasted two or three weeks. The abscess which re-

sulted, instead of breaking externally, notwithstanding poultices to promote it, discharged very freely through Wharton's duct. There was a continuous discharge of pus through that duct until May 29, 1882, when he called at my office for treatment.

An examination showed the gland to be a very little larger than normal, and indurated. Pressure on it caused pus to flow from the outlet of the duct near the frænum linguæ. An ordinary silver probe passed readily along the course of the duct to the gland. The touch revealed either necrosed bone or a calculus, the removal of which I assured him would be necessary before he could recover.

As he had consulted several other physicians, and used various remedies without benefit, he consented to an operation. This consisted in cutting into the gland from the inside of the mouth with an ordinary bistoury, wrapped with a roller bandage except at the point. The end of the probe, passed through Wharton's duct, served as a guide. When the opening was large enough, I introduced a pair of bullet forceps and removed two calculi. The larger is irregular in shape, with a smooth surface on one end; the remainder of the surface is quite rough. It is thirteen millimetres long, eight broad, and seven thick. The smaller is flat shaped, smooth on one side, where it probably rested against the other. There is a similar smooth place on the end of the larger, which corresponds in shape and surface with this. It is rough on the other side and edges. It is seven millimetres long, five broad, and two thick. They are dirty brown in color; the rough projections lighter than the dark background; very hard, having the appearance of brown quartz on the smooth surfaces. Internally the larger one is snowy white. It shows under the microscope an amorphous scaly detritus, many of the fragments having the shape of the epithelium from the mucous membrane of the mouth, but no definite forms of crystallization.

At the time of writing the patient is entirely well. The duct is larger in calibre than normal; and the gland secretes what appears to be healthy saliva, which can be pressed out through the duct.

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—The annual address of Dr. H. O. Marcy, President of the Academy of Medicine, which has appeared, treats of the recent advances of sanitary science, and the relations of micro-organisms to disease. It is a carefully prepared paper.

—The "Mid-winter" number of *The Century* is one of unusual interest. The frontispiece, "Head of a Man," by Rembrandt, from a St. Petersburg collection, is an exceedingly fine engraving, and is the subject of an article by Richard Whiting. The illustrations generally are more than usually effective, and are on especially good paper.

We have only space to mention a few of the authors and their articles to show the value of this number: Signor Salvini's "Impressions of Shakespeare's *Lear*," Geo. W. Cable's "Dr. Sevier," and a practical statement of "The Convict Lease System." An interesting little article on Keats, by Stedman, and articles on Dante, by Miss Sarah Freeman Clarke and Christina Rossetti; Titus Munson Coan's sketches of Gustave Corbet, and General Badeau's sketch of General Phil. Sheridan, with a fine engraving of the General. These are a few of the articles of interest. The quality of the articles is superior to their titles, and the number is peculiarly rich in its illustrations.

—*Harper's Monthly* for February is a model number both in text and illustrations; the latter of unusual beauty and delicacy. We can but give the titles of some of the various articles. "The Upper Thames," by Joseph Patton; "The Possibilities of a Revived Industry," by Alfred F. Oakey; "A Winter in Canada," by C. H. Farnam, and the continuation of the serials, "Judith Shakespeare," by William Black, "At Mentone," by Constance Fenimore Woolson, and "Nature's Serial," by E. P. Roe. There is the usual number of poems and shorter articles, with the always valuable "Topics of the Time," and "Open Letters."

—*St. Nicholas*, the prince of magazines for young people, comes each month more and more attractive. The names of the contributors alone are sufficient to assure one of the excellency of the articles it contains. In the January number alone we find Louisa M. Alcott; Rose Hawthorn Lathrop; Julian Lathrop; William O. Stoddard; Mayne Reid, and H. H. Boyesen, with quite a number of lesser lights, making a galaxy of unusual brilliancy.

—*Littell's Living Age* gives every year increased proof of its being fully alive to the demands of the best culture. There is nothing that can take its place as a representative of the choicest literature of the day, and a family without *Littell's* is without one of the most educating of American periodicals.

Our other weekly exchanges are among the best of religious and secular newspapers. The *Independent*; the *Evangelist*; the *Presbyterian Banner*, the oldest Presbyterian newspaper in the country; the *Presbyterian*, and the *Methodist*. Of the family newspapers, the *Germantown Telegraph* always stands first, and the change in ownership and editorial management has added to its vivacity and general tone. The *Vermont Journal* and the *Trenton Gazette* are both papers of much value.

BOOK NOTICES.

Transactions of the American Gynecological Society, vol. 8. For the year 1883. New York. Dr. Appleton & Co., 1884. 8vo., pp. 275.

It will perhaps answer the purpose of a notice of this volume to state what it contains, as the society which issues it, is now so well established that all that it publishes has an acknowledged merit. After the minutes and the President's annual address, which is a biographical sketch of Dr. Nathan Smith, founder of Dartmouth Medical College, we have the following papers: "Superinvolution of the Uterus," by Dr. J. T. Johnson; "Cleanliness in Surgery," by Dr. R. S. Sutton; "Hot Water in Secondary Hemorrhage after Pelvic Operations," by Dr. A. H. Smith; "On Dysmenorrhea," by Dr. C. D. Palmer; "A Rare Form of Abdominal Tumor," by Dr. T. A. Reamy; "A New Mode of Operating for Anal Fistule," by Dr. E. W. Jenks; "Congenital Fissure of the Urethra," by Dr. H. F. Campbell; "Injuries of the Gravid Uterus as Complications of Laparotomy," by Dr. C. C. Lee; "Is the Extirpation of the Cancerous Uterus a Justifiable Operation," by Dr. A. R. Jackson; "On Perineal Laceration," by Dr. T. A. Emmet; "Chronic Abscess of the Pelvis," by Dr. W. H. Byford; "On Ergot," by Dr. G. J. Engelmann; "Rectal Disease in Relation to the Uterus," by Dr. R. B. Marvin.

The volume is very handsomely manufactured, but we miss the bibliography of gynecological literature as prepared for preceding volumes.

A Manual of Practical Hygiene. By Edmund A. Parkes, M. D., F. R. S., etc. Edited by F. de Chaumont, M. D. Sixth edition vol. ii.

Diseases and Injuries of the Horse. By F. O. Kirby. Wm. Wood & Co., New York City.

The above volumes are numbers of Wood's Library of Standard Medical Authors.

Of Parkes' treatise we have already spoken on the occasion of the appearance of the first volume. It is a work of sterling merit, and has been edited with much care. It contains a vast amount of information such as could with difficulty be obtained elsewhere.

The work of Kirby is of less importance. It impresses us as hastily put together, a compilation without judgment, and by one with no practical knowledge of the subject—very much out of place in a pretended "Library of Standard Medical Authors." It is evidently intended to fill a gap at little expense to the publisher and no profit to the purchaser, and is, therefore, and evidently make-shift.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,

ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

HEREDITY.

Can we ever hope for the Utopian days when the enigmatical phenomena of heredity will be clearly comprehended?

That heredity is a fact, that form and feature, and oftentimes peculiarities or idiosyncrasies of functions are transmitted from parent to offspring, we all know; but the hidden and intensely interesting points of relation between father and son, or in other words, the whole history of heredity, is as yet a sealed book, destined to reveal most interesting and important facts, when the master mind arises who can unfold them to us.

We are aware that the tendency to certain diseases passes from one generation to another, and we lean very much to the proposition that *all* diseases characterized by change of form or permanency of function of any organ, or organic disease, are capable of transmission from sire to son.

But, and here comes in a most important practical point—we cannot accept hereditary influence as an absolute and single potential factor in the transmission of disease; it would seem rather that we must regard it as the predisposing cause, which by itself is not capable of causing disease, being dependent for the fullness of its mission upon collateral exciting causes; in other words, hereditary tendencies can be obliterated.

For example, let a child inherit a consumptive tendency from a parent who has died of phthisis. If, from early infancy, his life be so guided by intelligent sanitary forethought, that his weak lungs may be protected from the exciting causes of phthisis, if his life be nearly allied to that of his remote roving ancestors, it is very probable that his hereditary weakness will be made strong, that he will escape the disease and that he will in turn transmit the tendency less markedly to his offspring, and so on, through successive generations, until finally the predisposition will become extinct.

Does it not seem reasonable to suppose that acquired tendencies may be transmitted, and that transmitted tendencies may be annihilated?

What is true of consumption is, very likely, true of all organic diseases; and in this lies a

strong argument in favor of a better and more general knowledge of preventive hygiene.

We have a fair knowledge of the exciting causes of organic diseases, and if, as we must logically concede, these exciting causes will act more potently, when a hereditary predisposition exists, then, *pari passu*, must we hold that if these exciting causes are avoided, the hereditary predisposition is greatly robbed of its power.

If our arguments are tenable, it would seem that the majority of cases of organic disease depend for their existence upon two factors: First, hereditary predisposition, and second, the exciting cause. And, further, it would appear that if the exciting cause be withheld, the hereditary tendency will become ultimately annihilated, and if the hereditary predisposition is not transmitted, the exciting cause has lost an ally of no mean significance, and its strength must be greatly increased in order that it may originate the disease.

Here, then, would come in the value of medical family histories. If the public would only sufficiently realize the value of preventive science, they might be induced to keep medical histories of their families, which would tend to throw much light upon the obscure subject of heredity, and would greatly aid the individual who desired to live a long and healthy life.

If each one of our readers had access to the medical histories of the families of his father and his grandfather and his great-grandfather, and so on for generations back, how many light-houses would he not have to warn him off the shores of heredity, and to indicate to him the enemies to health that had come to him from his ancestry.

There are objections to this plan, some great, others trifling. Among the first, stands prominently the almost insurmountable objection, that but few men could be found who would be willing to state on paper that they had contracted syphilis; among the latter, we would be met with the objection that "it was too much trouble."

Therefore we fear that, valuable as such manuscript would prove in the maintenance of health and the promotion of longevity, it cannot be an

accomplished fact, save among the very few who value science and the general welfare above all personal considerations.

Yet we must all concede the value of such histories, and we should, as far as lies in our power, cause those who look to us for advice, to so regard them.

THE EFFECTS OF DISEASED MEATS.

The excitement about the "American hog," will be productive of good results if it forces the owners of stock to take better care of their animals. Instead of talking about making reprisals on France and Germany because they exclude the American pork, it would be more to the purpose to appoint a committee of experts, and prove by their showing that the pork we send abroad does not carry disease with it. Or, if the finding of the committee were to the effect that any considerable proportion of the meat actually is trichinous, or for other cause unfit for food, then certainly we ought not to find fault with our European neighbors for not choosing to be poisoned for the sake of benefiting our pork-packers.

Why has not this simple and inexpensive plan been consistently and steadily pursued? The answer made by the European journals is that we do not dare to have an honest and competent examination of our pork products. They will have a right to say so, until the contrary is shown by our actions.

The reply frequently made to the European charges is that while pork enters largely into our home consumption, cases of trichinosis are more rare here than in Germany, and that epidemics of it, such as have recently been reported in Saxony, are unknown.

On the surface, this is true; but it is also true that trichinosis strongly simulates other diseases, as in its lighter forms muscular rheumatism, and in its graver manifestations typhoid fever, so that it is always possible that many cases pass unrecognized by either patient or physician. We are certainly much less on the alert for its outbreak than are the medical men of Germany.

Another and a more satisfactory explanation of

its rarity in the United States, is the habit of our people to cook their food thoroughly. At country hotels and farm-houses we have almost invariably found the meats "well done," often over-done—roast beef, for example, being exposed to the fire until it was browned through and through. This is a sad infringement of the canons of gastronomy, but it is an excellent prophylactic against tape-worm and trichinæ.

In Germany, on the other hand, smoked ham and bacon are eaten absolutely raw, and in France many meats are persistently underdone to a degree that requires a special education to enjoy them. In the restaurants of Paris and Berlin it is no uncommon thing to see a person order a *bijsteck au naturel* with a *sauce tartare*, which is little else than a piece of absolutely raw beef with a mustard dressing. Of course, any ova or germs which find their habitat in muscular tissue are thus conveyed, active and unchanged, into the congenial nidus of the alimentary canal.

These differences in culinary customs suggest a reason for the greater extension of parasitic disease in Europe than in the United States. Nevertheless our duty and our interest are to put every safeguard against the possibility of injurious entozoa. Experience has demonstrated that cleanliness, proper feeding, and occasional alteratives, will keep stock in entire health; and this should be impressed on stock-raisers by emphatic measures. They have no right, we have no right, to jeopardize the health of a community in order to put a few more pennies in the purse.

THE QUESTION OF WOMEN DOCTORS.

We like to hear and present all sides of the questions which are actively interesting the profession. Hence it gives us pleasure to publish the following comment on a recent editorial in this journal:

DEAR SIR:—It is all very well to advocate the chivalrous sentiments about women doctors, as in your last number. But take my case. I have a wife and children to support, and practice in a village of about 2,000 souls. Recently a woman doctor came here, whose husband has a good position on the railroad. They have no children.

She went to work, and by talking to the ladies, has secured a large share of the best family practice. Is it right that we should encourage those who support no one thus to rob us of our livings? Is this fair to the great body of male physicians?

* * * * *

We acknowledge there is force in this argument; at least, there seems a certain cogency in the reflection that the position assigned woman by the customs of our social life gives her an advantage in the struggle for existence against the stronger sex, handicapped as the latter is by heavy responsibilities. To be sure, we may ask, is not an unmarried man equally free from responsibilities, equally light and girded for the race? But in our profession the fact is well known that it is not easy for an unmarried man to secure family practice, which is precisely the most profitable; while a woman, married or unmarried, has the entrée to families and finds no bar to her reception.

Related to this is the great, the often absurd, modesty of American women. Social custom does not permit them to refer in society to such things as childbirth, which European ladies speak of without the least hesitation. A woman physician can readily take advantage of this, to prejudice her sex against male physicians. We have seen and heard the argument used that all diseases peculiar to women should be treated by women. This would carry with it the children; and without women or children to treat, what would become of most doctors? There is unquestionably a growing sentiment from this cause against male physicians, and it is fostered by the advocates of female physicians. Suppose it increases for a few decades, and suppose the supply of female practitioners is largely increased, as it is likely to be, what will be the result? It can hardly fail to be otherwise than seriously detrimental to the career of medicine as a business for men.

Granting this, is it a proper reason for us to oppose the medical education of women? In some trades which could be successfully prosecuted by women, type-setting for example, the trades unions have felt themselves justified in preventing women from learning the trades, on the ground

that they reduce wages, and thus hinder a man from supporting his family.

The answer to the above question need not concern us. We do not, as a profession, have the power to stop women from becoming doctors, nor can we prevent them getting into practice. To inveigh against them in journals, and to exclude them from medical colleges and medical societies, will not check their inroads. Therefore we may as well receive them with the best grace we can, and shun all appearance of persecution. In the new forms of social life toward which man is drifting, the position of the sexes will be fixed by their relative capacities, and by their respective fitness for certain occupations. We can do little to retard this, nothing to prevent it; and while we sympathize with the writer of the above, and with others in his situation, we do not know of any more comforting words to give than those above written.

THE BOWER AND KEATES CASE.

This celebrated case, which has attracted so much attention in England, is well worthy of imitation the world over.

These two gentlemen were subjected to a most unjust and malicious prosecution for malpractice, the circumstances being such as might happen at any time to any of us. With pride we note that the whole profession of England immediately rushed to their rescue, and subscriptions to the defence fund poured in so rapidly that the demand has been much more than supplied.

In this connection we are pleased to see that a circular has been sent to the profession of this city, under the signature of two of our most eminent surgeons, asking for contributions to reimburse Dr. Forbes for the heavy outlay (\$4,000) he incurred last winter in his defence of the prosecution charging him with complicity in the stealing of bodies from Lebanon Cemetery.

—Rev. R. Heber Newton, in a paper on the "Obligations of Society Towards the Insane," pleads for schools for the special training of nurses for the insane.

NOTES AND COMMENTS.

Extractum Pancreatis in Typhoid Fever.

We all realize that the dietetic treatment of typhoid fever is exceedingly important. Therefore we are prepared to realize the importance of the recommendation made by Dr. Frank C. Wilson in the *American Practitioner* for January 1884, that the milk given to typhoid patients should be first digested with extractum pancreatis. Milk so treated cannot be coagulated by even the strongest acids, its casein being transformed into peptone, and in a condition to be at once absorbed and assimilated. There is noticeable a slight bitterness, to which the patient soon becomes accustomed, so that it is taken readily and produces no discomfort. Even this bitter taste may be avoided by stopping the process of digestion before it is entirely completed. It has been found by experiment that the objectionable taste is only developed when the casein is entirely peptonized. It is scarcely ever necessary to carry the artificial digestion quite so far, and when stopped at any point before completion the taste is perfectly natural. If immediately placed on ice, it can be kept as long as simple undigested milk. The ferment of the pancreatic extract is held in a latent condition, and when taken into the intestinal canal may still further aid in the completion of the digestive process.

To avoid the possibility of the patient becoming tired of the same article of diet day after day, its form of administration may be varied in a number of ways. As the casein is peptonized, and can not be coagulated by even the stronger acids, the milk so prepared can be utilized in making milk punch. This can be flavored with lemon-juice or any other acid desired. Thickened with gelatine, sweetened and flavored, it forms a delicious milk jelly suitable for convalescent patients and grateful to the taste.

During the past two years he has met with many instances in which the use of the pancreatic extract has yielded the most gratifying results. Not alone in typhoid fever is it useful, but in all instances where the digestion is enfeebled, or where it is interfered with by the presence of ulcerated or inflamed surfaces, the process of peptonizing the food will be found of service. In rectal alimentation its importance is manifest, the food so prepared being readily absorbed and appropriated without inconvenience or irritation. He has sustained patients with gastric ulcer entirely by nutrient enemata twelve or fourteen

days. In this time the ulcer will be entirely healed, so as to allow the cautious administration of peptonized milk in gradually increasing quantity, until a full meal can be taken.

Antiseptic Inhalations in Phthisis.

This method of treatment is not particularly new, but its use has been deprecated by many, on the grounds which are noted by Dr. I. Burney Yeo in the *Brit. Med. Jour.*, January 12, 1884, as follows:

"Two objections have been made to the use of antiseptic inhalations, which are in singular opposition one to the other.

"The first is, that the vapors given off from the fluid which we drop on the sponge of the respirator are so strong and irritating, that they excite inflammation of the pulmonary tissues, and thus do injury; indeed, I have seen the antiseptic treatment of phthisis referred to in a medical journal as 'homicidal.'

"The other objection does not accuse of homicide, but is content with pointing out that we are very foolish people to imagine that any useful or appreciable amount of our antiseptic substances reaches the lung at all! I do not know which of these objections is least in accordance with experience.

"With regard to the first objection, I can state most positively that I have never seen any symptoms of irritation set up by antiseptic inhalations when properly applied. With sensitive persons, it is desirable to begin by at first dropping a very few drops of the inhalant on to the sponge, and slowly increasing the quantity; by that means, you will avoid all risk of irritation.

"The second objection scarcely needs answering at all; to some extent, it is a resurrection of the old dispute as to the use of topical remedies (in the form of vapors and sprays) to the respiratory surface, which was agitated fiercely many years ago, and the affirmative view thoroughly established by most elaborate and careful experiments by a number of observers in every country in Europe. The dispute and its results are fully related by Oertel in the work already referred to, and also by Dr. Solis Cohen, of Philadelphia, in his work 'On Inhalations.'"

He has had good results, and after reading his paper, we would feel inclined to give a trial to the inhalation of a weak solution of corrosive sublimate, say 1 to 2000 or 2500, by means of a steam atomizing apparatus. *New Surg. Reporter*

Diagnosis and Pathology of Dermoid Cysts of the Ovaries.

In answer to a question, Dr. Gannett (*Boston M. and S. Jour.*, January 17, 1884), stated that if hair is found the diagnosis is easy enough; it is difficult to get hair through the exploring needle, but fat comes, and this is diagnostic, particularly in the region of the ovary.

As to the pathology, it was originally supposed,

fifty years or more ago, that dermoid cysts represented the results of an ovarian pregnancy; and where such tumors were found post mortem in unmarried women, serious aspersions were raised against the moral character of the individual. But as later similar tumors were found in young children before the age of puberty, and further in the male testicle, it became obvious that some new theory of their origin was necessary.

In later years they have been thought to be congenital; that during foetal life a portion of embryonic tissue remained in the ovary, and later developed into a dermoid cyst.

Recently Waldeyer has advanced the idea that as any ovarian epithelial cell may become an ovum, so any such cell may develop into one of these tumors.

Dr. Gannett mentioned the fact of the association of dermoid cysts with other tumors of the ovary, he having observed two cases of combination of sarcoma with dermoids, and three cases of dermoid cyst in connection with well-marked cystomata.

On School Hygiene.

This was the subject of an address before the American Health Association, at its last meeting, by Dr. Charles J. Lundy, of Detroit. He sums up tersely as follows what is required to remedy existing defects:

1. Avoid the cramming process in education, and the nervous excitement due to the spirit of rivalry.
2. Reduce the number of subjects in the curriculum, and shorten the periods of study.
3. Ventilate the school-rooms in accordance with the most approved methods.
4. Regulate the temperature of the school-room—an atmosphere which is too warm debilitates the system.
5. Provide properly constructed and arranged seats and desks.
6. Instruct pupils to sit erect, and to hold the book or paper at least twelve inches from the eye.
7. Provide highly myopic pupils with proper spectacles, which will enable them to read at the natural distance of twelve inches.
8. Furnish pupils with well-printed books.
9. Furnish abundance of light, without producing glare. Let it come from the left side if the room is narrow, from both sides if the room is wide.
10. Provide for the physical education of school children, and teach them the importance of outdoor exercise.

Bromethyl in Childbirth.

The investigations of the effect of bromethyl in childbirth have demonstrated that we possess in any of the ethyls of bromine a remedy of the greatest value in the delivery of women. Its greatest advantage seems to consist in the fact of its causing local anæsthesia without loss of consciousness. Recently Dr. l'Parnemann (*Allg. Med. Centr. Zeit.*, No. 86, 1883,) has instituted a series of researches, which appear to prove definitely, that under the influence of bromethyl the labor generally progresses more regularly, the single contraction of the uterus endures longer and is more powerful, that the frequency of the pulse suffers no alteration, and that there is perfect local anæsthesia.

There is another benefit which we seem to derive from this remedy in childbirth, viz., the rapidity of its effect. The writer quoted has established the fact that usually, at the first inhalation of the drug, about ten deep inspirations are sufficient to establish local anæsthesia, while during the later inhalations two deep inspirations mostly answer their purpose, to make the labor painless.

The delivery may be concluded by the application of the forceps, and even the latter causes almost no expression of pain. The patients were conscious during the whole time, yet totally free from pain, and in no case have been noted disagreeable consequences.

Another Case of Long-Retained Pessary.

Of interest in connection with the case we recently reported, we note that Herbert Renshaw relates (*Brit. Med. Jour.*) the case of a lady, aged 55, who consulted him complaining of severe pain in the back and legs, and unpleasant vaginal discharge. She also was obliged to pass her motions in the upright position, owing to the intense pain caused by any attempt to relieve the bowels in a sitting posture. On examination a smooth raised fleshy ridge was found, running from before backward, on each side of the vagina, terminating before and behind in a rough semi-circular ridge. Fourteen years previously the patient suffered from a troublesome bearing down. She consulted a "wise woman," who introduced a ring, and asserted that it would never require to be removed. For many years she obtained great benefit from this support. The ring was removed by shelling it out from the fleshy overgrowth, by picking through with the finger-nail. Half an hour after the operation, all her pains disappeared. There was incontinence of urine, and no fecal matter in

the vaginal discharge. From the mineral earthy deposit on the surface, it appeared to have been coated with lime-salts.

The Benignity of Venereal Disease.

One of our English exchanges states that in a return made to the House of Commons in 1877, No. 260, it is mentioned that in English work-houses in twenty counties there were but forty-one cases of venereal disease, and in twenty-nine counties there had been only seven deaths from the disease. "The deaths from syphilis at all ages among paupers, including infants, children, and adults, were only eight per million, which was not quite one in one hundred thousand, and among the general population not more than one in one hundred and twenty thousand."

With regard to the benignity of modern cases of syphilis, Dr. Taylor quotes Fournier that "in ninety-five per cent. of all cases of true syphilis met with, the disease is truly benign," and Lancereaux, who says: "It should be known that this disease becomes dissipated in a great number of cases after the cessation of the cutaneous eruption, and sometimes even with the primary lesion."

Prolonged Gestation.

Is it possible? can gestation extend for a longer period than that usually accorded to it? There are many distinguished men who consider that it is impossible, and look upon all such cases, as due to errors in calculation.

The following case, however, which Dr. Ballard reports in the *Brit. Med. Jour.*, January 12, 1884, seems so conclusive as to hardly admit of question. He says:

"I have just attended a girl, aged 16½ years, the duration of whose pregnancy was 306 days, or 44 weeks with the exception of two days. I have been very careful to guard myself from error with regard to this case, and I believe it may be accepted with every confidence as a reliable contribution to the statistics on this subject. The pregnancy was the result of a single intercourse. The labor was short and easy for a primipara, and the child quite within the average as to size."

Trichinosis.

At the last quarterly meeting of the Illinois State Board of Health, three outbreaks of trichinosis—one of them resulting in three deaths—were reported, the first during the early part of November, in a family near Gardner, Grundy

county; the second and third during December, in Woodburn, Macoupin county, and in Bloomington, respectively. The Gardner and Bloomington cases resulted from eating uncooked pork and sausage, and the Woodburn cases from raw smoked sausage. Specimens of the meat from Gardner and Woodburn were sent to the secretary for examination, the character of the disease being only suspected, until the microscope showed, in one case, about 2,000, and in the other, about 8,000 trichinæ to the cubic inch.

More About Jequirity.

To the Ottawa Medico-Chirurgical Society, Dr. Prevost communicated the results of some experiments with "*Jequirity*" in the treatment of granular lid, exhibiting some samples of the drug. It is especially indicated in cases of trachoma, where pannus is a marked symptom. Eight beans are placed in four ounces of cold water, and four ounces of hot water added. The granulations are painted with the solution, and the patient told to wash the lids every day, allowing a small amount to penetrate beneath the lids. It acts as an irritant, causing an œdema and purulent discharge in some cases. When these acute symptoms subside, the eye is found to be free from the troublesome disease. He had used it in several cases with success.

Perspiration in Albuminuria.

Dr. Janssen (*Deutsch Archiv. f. Klin. Med.*) finds that nephritic patients constantly lose large quantities of watery vapor from the skin, but no regularity can be observed in the quantity. Œdematous parts of the body lose more water than non-œdematous parts. Less water is lost by perspiration in acute nephritis, and possibly also in nephritis with contracted kidney. The proportion differs in different individuals suffering from nephritis with enlarged kidneys; they sometimes lose more, and sometimes less, than healthy patients. No regularity could be found in the excretion of carbonic acid by the skin in nephritic patients.

Alcohol vs. Strychnia.

As the result of a recent discussion before the French Society of Temperance, it would seem that while strychnia will control the functional, it has no effect on the organic influences of alcohol, so to speak. In other words, if a person under the influence of alcohol is strychnized, he will not appear to be drunk, but all the same will the results of alcohol, such as cirrhosis of the liver, become manifest.

SPECIAL REPORT.

NO. XV.—OPHTHALMOLOGY.*

BY C. S. TURNBULL, M. D.,

Oculist to the German Hospital, Philadelphia.

(Continued from page 158.)

Case of Tuberculosis of the Iris. Wiener. Med. Bl., No. 24, and Sitz. Ber. d' Gez. d' Aerzte, p. 750.

In a girl of twelve, Arlt saw the iris of the right eye densely covered with grayish, non-vascular nodules, presenting the characteristic appearance of tubercles, and filling the whole anterior chamber. Vision proportionately diminished. Examination of lungs shows tuberculosis beyond a doubt. Hereditary predisposition.

Tubercule Primitive de l' Iris et du Corps Vitri. Soc. de Chir., séance, 14 Juin, 1882, Union Med., No. 83.

Poncet made a similar observation in a person of sixteen without any hereditary predisposition, and with healthy lungs. No syphilis. Tuberculosis of the iris and anterior portion of the vitreous. The author thinks the latter is not rare, and agrees with Trelat and Perrin in advising the removal of an eye with tuberculosis of the iris, so long as other organs are not affected. An enucleation for tubercles of the choroid should only be performed when there is inflammatory reaction or danger of infection of the surrounding parts.

Primary Tubercle of the Iris. Trans. of the Ophth. Soc. of the Unit. Kingd., vol. ii., p. 259.

Swanzy excised the eye of a girl two years old; five months later the child was in good health. Marked tubercular family history. Microscope confirmed diagnosis. S. discusses the case with reference to the inoculation or infection theory.

On Genuine Tuberculosis of the Vitreous in Man. Deutschman frequently found pure tuberculosis of the vitreous in rabbits, without any of the choroid and retina, after injection of tuberculosis matter. The author also found, in a case of amaurosis of a man, due to iridochoroiditis, by microscopic examination, that it had been preceded by localized tuberculosis of the vitreous, the other membranes of the eye not being affected.

Case of Pure Gumma of the Iris. 5 Lustren Ophth. Wirksamkeit., p. 133. Wiesbaden: Bergmann.

Mooren had an opportunity to examine microscopically a pure gumma of the iris in a young man of nineteen, in whom syphilitic antecedents could not be traced. He found besides the char-

* From the Progress of Ophthalmology During the Second and Third Quarter of the Year 1882, by H. Magnus, of Breslau, and Others.—*Archiv. Ophthal.*, vol. xii., No. 1.

acteristic structure, great masses of pigment in form of lumps, generally lying together in heaps, but not enclosed in cells.

Among two thousand and sixty-eight cases of iritis, the same author observed one hundred and sixty-nine of pure syphilitic iritis. If, after a regular iridectomy in chronic irido-choroiditis, symptoms of irritation are observed, which combined with marked distension of the blood-vessels threaten closure of the pupil, he would diagnose syphilis with certainty.

Scollamento dell'Iride. Bell. d'Ocul., vol. v., No. 1, September, 1882.

Moyne. Two cases of traumatic irido-dialysis in two boys twelve years old. The first healed by iridesis, with $V=1$; in the other, the lens also was injured, but successfully extracted. Double vision was not found in either patient.

Iridermia. Path. Soc. of Dublin. British Med. Journ., May 6, 1882, p. 663. Benson exhibited at the Pathological Society of Dublin the right eye of a boy æt. ten. Globe enlarged. Cornea clear. Lens subluxated and opaque, with here and there calcareous patches. Iris entirely absent, except a small sector above, which was adherent to lens capsule. Lesions probably due to intra-uterine irido-choroiditis. Iris of left eye normal.

Case of Sarcoma of the Choroid. Archiv. Ophthal. vol. x., p. 269. Arch. f. Augenheilk., vol. xi. 3, p. 323. Ayers observed a melano-sarcoma of traumatic origin. The microscope showed active proliferation of the cells by division, and considerable thickening of the walls of the blood-vessels—the latter probably the result of proliferation of the adventitia and the perivascular tissue of the blood-vessels.

Melano-sarcome de la Chorioide. Ann. de la Soc. de Med., d'Anvers, May-June, 1882. Le Roy. In this case also the sarcoma seemed to be of traumatic origin. Later a relapse occurred in the orbital tissue, making exenteration of the orbit necessary.

The Etiology of Hydrophthalmus. C. f. D., vol. vi., p. 225. The case of Mayerhausen was one of congenital hydrophthalmus, whose further development coincided with the beginning of dentition; it gradually attained considerable dimensions, while at intervals inflammatory attacks of an exquisitely glaucomatous character set in, and finally led to nodular deposits on the anterior surface of the corneal epithelium. The size of the globe was reduced and vision improved by the use of eserine, as in an analogous case of Bergmeister (Wien. Med. Presse, 1881, No. 30).

Alcune Considerazioni sulla Etiologia del Glaucoma. Quadristat e frammenti d. Oftal., Roma, 1882. As regards the etiology of glaucoma, Angelucci seeks its primary cause in the sclerosis of the arteries, giving rise to stasis in the veins and 'consecutive exudation in the venous walls. The closure of the perivascular lymph-ducts by the swollen veins is of greater consequence than the closure of Fontana's canal.

On Eserine and Pilocarpine in Glaucoma, and Eserine in Ocular Neuralgia. Snell is satisfied that eserine is of use not only in acute, but also in chronic glaucoma. Its action is not so certain in the latter, but still it sometimes not only produces an improvement in the vision, but also arrests the progress of the disease. He records a case of acute glaucoma where iridectomy was declined, and not having any eserine at hand, he ordered pilocarpine "discs." The same evening the patient was much relieved of pain, and a few days later the attack passed off. He has found eserine of great use in cases of ocular neuralgia, unattended with increased ocular tension. To avoid the danger attending the use of atropine in eyes with a tendency to glaucoma, Streatfield proposes the introduction into the British Pharmacopœia of a much weaker solution in addition to the present one. He believes the present scare about the artificial production of glaucoma by use of mydriatics to be much exaggerated, but it ought to be better known that a very weak solution suffices for the production of mydriasis.

On a Case of Sympathetic Ophthalmia. Ophth. Hos. Rep., vol. x., August, 1882, p. 322.

Critchett. A man received a gunshot wound in the right eye in the ciliary region. Palliative treatment at Provincial Hospital for a fortnight, then admitted into St. Mary's Hospital under Mr. Anderson Critchett. O. S. appeared to be perfectly healthy, and V. normal. O. D. enucleated. Patient discharged six days afterward, with caution regarding use of O. S. Fifteen days later, exactly one month after injury, noticed slight indistinctness of vision, which gradually increased. Eye became red and painful. About five months later was readmitted to the hospital. Well-marked sympathetic ophthalmia, with + T2. Iridectomy performed with improvement of V. C. refers to opinion which was held by ophthalmologists up to a recent period, namely, that when an injured globe was removed before any evidence of irritation could be noticed in the other eye, complete freedom from sympathetic ophthalmia might be confidently predicted. This doctrine, as he remarks, has received a rude shock from the recent

observations of Mr. Nettleship. The practical inference is, that a short delay may be fraught with danger, and that an emphatic decision should, if possible, be at once arrived at as to the necessity which exists for removal of the injured eye.

On the Transmission of Sympathetic Affections. Five Lustra of Ophthalm. Practice. Wiesbaden., Bergmann, 1882, p. 143.

Mooren believes that the sympathetic irritation is transmitted through the ciliary nerves and optic nerve, especially through the agency of the vaso-motor system. No definite date for the time of its beginning can be given, though the inflammation may set in before the time generally accepted, *i. e.*, the fifth week. In only three cases did Mooren see sympathetic neuritis or neuro-retinitis resp. develop after timely enucleation.

Distribution de la Cataracte dans la Région Lyonnaise. Assoc. Franc. pour l'Avancement des Science. Sess. de 1882, à la Rochelle. Progr. Med., Sept., 1882; Gaz. d' Ophth., vol. x., 1882.

In regard to the distribution of cataract in the neighborhood of Lyons, Gayet reports that they occur in about the ratio of 2 to 1,000. They are less frequent in women than in men. Senile cataract develops in the latter at forty-four, in the former at forty-nine. Cataract is more common—more than 3 to 1,000—where glass-blowing and metallurgy is carried on, a fact which he ascribes to the radiating heat. The number of peasants with cataract is comparatively large.

Gliomatous Infiltration of the Lens. Archiv. Ophthal. vol. x., p. 275. Arch. f. Augenh. u. O., vol. xi., 3, 327, with an illustration.

Ayers found in a glioma of the retina (fr. Arch., f. Augenh. u. O., vol. x., p. 325), that the glioma-cells extended on one side of the ciliary body, canalis petiti, along the whole length of the suspensory ligament to the lens-capsule, had penetrated the latter, and entered the lens itself.

On the New Formation of Bone in the Lens-Capsule. loc. cit., vol. x., p. 275. Arch. f. Augenh. u. O., vol. xi., 3, p. 327.

The same writer found in a case of new formation of bone in the lens-capsule, that the cortex had entirely disappeared, and had been replaced by bony tissue. Ossification begun in the layers of the lens parallel to the stratum of connective tissue near the capsule. The latter had about its normal convexity.

Preliminary Iridectomy in Extraction of Cataract. Brit. Med. Journ., September 2, 1882, p. 424.

For the last six years Hodges always performs preliminary iridectomy before extraction, is very well satisfied with the results, and considers its

chief advantages to be the freedom of the anterior chamber from blood after extraction, and the information obtained by the operator as to how the patient bears narcosis.

Cataract Operations at the Clinic of V. Arlt, from 1874 to 1881. Wien., Med. Wochenschr., Nos. 16-18.

Schneidler has prepared the statistics of the cataract operations performed at the clinic of v. Arlt from 1874 to 1881. 1,547 peripheric extractions were performed in 1,460 persons. Good results were obtained in 91.2 per cent.; dubious in 6.44 per cent.; and loss in 2 per cent. The statistics of the accidents, of the operations and of the course of healing are very interesting.

Glioma of the Retina. N. Y. Med. Jour., June, 1882, p. 633.

Agnew observed a glioma of the retina, or rather gliomatous degeneration of the whole eye, in a boy of six months, which necessitated enucleation. One and a half years later glioma of the other eye, which was also enucleated. Nine years later, no relapse.

On Glioma of the Retina. Arch. f. Augenh. u. O., vol. xi., p. 413.

According to Vetsch, glioma occurred in the Zurich ophthalmic clinic in 0.03 per cent. of all cases (in Berlin 0.05 per cent.) Report of twenty-four cases, with special regard to their termination. Both sexes are afflicted to the same extent, neither is there any difference in the side. Congenital glioma was observed in three cases, in each unilateral; in the first and second years it occurs twice as often as in the next six years put together. In regard to its cause nothing definite could be determined. A particular new and characteristic symptom, observed in seven cases, or 32 per cent., was megalocornea, which must be referred to increased tension. In nine cases no operation was performed; death ensued in these on and after sixteen months. Of thirteen who were operated on, five lived, eight died. In five cases there was a relapse in the orbit, in one with scleral perforation in the parotid after three years, in another, after the same length of time, in the eye. Two were cured (no relapse after seven and nine years respectively). In recent cases the microscope revealed, besides round cells, a number of cells with two and more offsets of various length, which Schultze has shown to be normal components of the granular and intergranular layers.

On Visual Disturbances after Loss of Blood. Deutsche Med. Wochenschr., No. 28, and Beitschr. f. klin. Med., vol. v., No. 2. In a woman of twenty-eight, Horstmann observed, four days after

abortion with profuse metrorrhagia, visual disturbances and concentric limitation of the field of vision, under the semblance of a slight neuroretinitis. He could observe its development from the very beginning. It terminated leaving sight slightly impaired, and an insignificant concentric limitation of the field of vision. He then gives a short historical sketch of visual disturbances after loss of blood, observed up to date. In almost all cases there was a more or less marked opacity of the optic nerve and the retina, or atrophic discoloration of the optic nerve. Sight was gained in only the rarest cases; the rule is lasting total amaurosis, or at least a high degree of amblyopia. In a few cases, one eye only was affected. He also reports visual disturbances after epistaxis, hemorrhage from the urethral mucous membrane, and after blood-letting, besides after bleeding from the digestive and genital organs. Nothing definite is known as yet as to the connection between the cause and effect.

Case of Cysticercus Cellulose in the Vitreous, Arch. f. Augenheilk., vol. xi., p. 396. Haase discovered a cysticercus in the right eye of a young man of twenty-one, upward and inward from the papilla, which entered the vitreous in the course of a few days. The parasite, which measured 17 mm. in length, escaped spontaneously through a meridional incision of the sclera, according to Graefe, 8-10 mm. long, with only slight loss of vitreous. No reaction. Vision was reduced to recognizing the motion of the hand at 2 to 3 feet. The author observed five cases of cysticercus among thirty thousand patients in Hamburg, two of which being sub-conjunctival, were easily extracted, while an operation was refused in a sub-retinal one, and another in the vitreous. Three years later, the latter had not yet destroyed the eye.

Epicritical Remarks on Operating for Cysticercus. V. Graefe's Arch. f. Ophth., vol. xxviii. 1, p. 187.

Graefe reports the results of twenty-four cases of extraction of cysticercus according to his method, in sixteen of which, by the smooth removal of the parasite, a perfect result was obtained as far as vision and other conditions were concerned. In eight cases in which the operation failed, the cysticercus lay either perfectly bare in the vitreous, with great freedom of motion, or it was surrounded by a number of membranous envelopes. He describes in detail the position and location of the parasites, the sub-retinal and those situated in the vitreous, the fixed and the movable. The last-mentioned are least suited for an operation. The sub-retinal ones are also difficult of removal, and the determination of their exact location pre-

vious to the operation is of the greatest importance. Graefe constructed a localizing ophthalmoscope for this purpose.

Un Caso Gozzo Esoftalmico. (Grave's disease). Osserv. Ottalm. Ann. Univ. di Med., No. 261, 1882.

Rampoldi observed a bilateral case of Graves' disease, in which exophthalmus did not develop until fifteen years after the swelling of the thyroid gland (on the left the size of a hen's egg) on the right of the head of a fœtus. Marked bruit over the heart and arch of the aorta. Graef's lid-symptom could only be detected when the patient rapidly looked downward. Vision normal, no arterial pulse in the fundus. The degree of exophthalmus is not given, but the lids could be closed. Rampoldi notes as a peculiarity a large number of pityriasis-spots upon the breast of this patient, as also of another, which extended to the abdomen.

Case of Metastatic Chlorosarcoma. Berl. Klin., Wochenschr., No. 33, 1882.

Behring and Wicherkiewicz describes a very rare case of metastatic chlorosarcoma, which was first noticed in the orbit of the right eye of an otherwise healthy young man of twenty-eight, caused exophthalmus, and was accompanied by choked disc of both eyes. Metastatic proliferation went on very rapidly, when vision diminished proportionately. The ophthalmoscope revealed, besides the characteristic symptoms of optic neuritis, peculiar dark striated thickenings of the retinal blood-vessels, whose origin was first ascribed to rupture, but proved to be neoplastic infiltrations of the walls of the blood-vessels. Two months later death ensued, after the patient had become completely blind, and severe cerebral symptoms had developed. The tissue of the neoplasm was found to consist almost entirely of round cells, somewhat larger than white blood-corpuscles, with large nuclei staining intensely; besides there were short spindle-shaped elements with similar nuclei, filled with numerous fat-granules. The cause of the bright green color which the sections of all these tumors presented, could not be determined either by microscopic or micro-chemical examination. The high percentage of chlorine in all parts of the tumors was very remarkable, and their green color may be fairly brought into connection with this. The tumor probably had originated in the sphenoid cavity, and had then proliferated into the nasal and orbital cavities, and into the right medial cerebral fossa.

Various Affections of the Eye, their Pathology and Treatment. Brit. Med. Journ., p. 811, March, 1882.

Mackuna considers that the cornea in small-pox becomes more frequently affected during the stage of scabbing, from the twelfth to the fourteenth day of the eruption, when the patient is getting over the secondary fever, as is associated with the formation of furunculous abscesses in other parts of the body in severe confluent cases. Constitutional treatment is one of the utmost importance in these cases. Locally he applies lint soaked in a lotion of belladonna, with sulphate of copper and tepid water. In the case of children, and some persons who find it hard to keep their eyes at rest, and also to prevent scratching, M. speaks in favor of Cellini's eye-protectors. These are zinc plates made of the same size as the eyelids, and fixed by means of an elastic band.

Hemeralopia in Affections of the Liver. Le Prog. Med., No. 23.

According to Cornillon, hemeralopia occurs in all kinds of affections of the liver, and probably is due to the icterus accompanying them. He reports three cases of simple hypertrophy of the liver, and of cirrhosis in the hypertrophic and atrophic stage. In each hemeralopia was at first but temporary, but later became persistent; once improvement after a diet of raw ox-liver (?). An ophthalmoscopic examination was only made in the first case, when a high degree of venous hyperæmia and arterial anæmia, combined with papillary œdema, was observed. V. and color-perception normal in good illumination.

CORRESPONDENCE.

The Responsibility of Drunkenness.

EDS. MED. AND SURG. REPORTER:—

The causes of drunkenness are two—exciting and predisposing. The exciting cause is the licensed public sale of the various compounds of alcohol; and the predisposing is a propensity inherited from parent or grandparent. The appetite is, therefore, either acquired or inherited. The laws of the federal, State, and municipal governments, from motives of revenue, offer every temptation to make drunkards, and to craze and madden citizens with every licensed allurement to drunkenness; but heartlessly refuse to admit the slightest excuse in extenuation of the violent acts of the drunkard's frenzied desperation. Some readily become drunkards, while others, however great the temptation, never become such. Governments cruelly tempt the drunkard's propensity to drink in order to get money by a license, and without either recognizing or appreciating it, spend twice the amount of money obtained by a license-law to sell the compounds of alcohol, to punish the drunkard for his mentally irresponsible acts, and to remedy the crime and pauperism that directly follow his yielding to the temptation which the

law proffers him:—thus suggesting that the responsibility of the toleration and perpetuation of drunkenness rests not upon those who *are* drunkards, but upon those who *are not* drunkards, and who have delegated to them, the right and power to make and repeal laws. Drunkards soon poison themselves unto death, but those who are not drunkards live after them and know the remedy.

Legislative duty indicates that the primary object of civil government is to foster the morality, vigor, and prosperity of the citizen, as a good parent cares for the welfare of his child. And can it be a judicious act of legislation, either federal, State, or municipal, that will, for the sake of gain from a license to sell intoxicating liquors, tolerate and perpetuate a temptation that leads to the crime, disease, and death of the citizen? It is a part of criminal law that the accessory to a crime is as guilty as the perpetrator; and if a government tempts the drunkard to indulge his propensity to drink by making such temptation a mere matter of license and revenue, and the drunkard, because of such temptation, drinks and makes himself insane, and commits murder, is not the government an accessory? The State tries and hangs the drunkard-murderer, and thereby presents the example of an accessory to crime turning judge and executioner of a criminal in whose act it was the prime tempter, leaving a fact showing the relation between the tempter and the tempted—the accessory and principal to crime. Legislative enactments have made it a seeming necessity to license an inducement to drunkenness, in order to get money to carry on the expenses of the government; and drunkenness will be assured so long as the people permit legislatures to legalize the public sale of the compounds of alcohol.

J. B. JOHNSON, M. D.

Washington City, D. C.

How to Take a Pill.

EDS. MED. AND SURG. REPORTER:—

The experience of W. S. Way, of the *Middletown Transcript*, Delaware, "taking a pill," suggests to me the probability that a plan I have used for several years with success, may be new to some readers of the REPORTER. Having noticed that if a person at meals inclined the head backwards, as in laughing, while there was food in the mouth, they were pretty certain to be strangled from "the food going the wrong way," I instructed those of my patients who had difficulty to swallow pills, to *keep* the head in the position they would if eating and swallowing food at the table—that is, the head inclined forward, the chin near the breast—and *keep* it in that position. If a small portion of saliva be on hand, or a small quantity of water taken after the pill is put in the mouth, it will surprise the patient and gratify the doctor to witness the facility with which it will be swallowed. To direct the patient to keep his eyes on his toes, I have found a help to keep the head in the proper position. SAMUEL E. WILLS, M. D.

Earlville, Cecil county, Md.

—A cremation society has been organized in Boston, and it is said that authority will soon be asked for to establish a crematory in the vicinity.

NEWS AND MISCELLANY.

Official List of Changes of Stations and Duties of Medical Officers of the United States Marine Hospital Service, October 1, 1883, to December 31, 1883.

Bailhache, P. H., surgeon. Relieved from duty at Cape Charles Quarantine Station, October 13, 1883. Detailed as member of Board to examine candidates for promotion, October 30, 1883. Granted leave of absence for thirty days, November 27, 1883.

Hutton, W. H. H., surgeon. Granted leave of absence for twenty days, October 1, 1883.

Wyman, Walter, surgeon. Detailed as member of Board to examine candidates for promotion, October 30, 1883. To proceed to Norfolk, Va., to investigate the conduct of the service at that port, December 31, 1883.

Long, W. H., surgeon. Leave of absence extended ten days, October 26, 1883.

Murray, R. D., surgeon. To proceed to Ship Island Quarantine Station, October 17, 1883. To inspect sites for quarantine stations, November 30, 1883. Granted leave of absence for twenty days, December 18, 1883.

Smith, Henry, surgeon. Granted leave of absence for twenty-five days on account of sickness, October 13, 1883. Relieved from duty at Norfolk, Va., October 17, 1883. To report to Surgeon Sawtelle, at New York, for temporary duty, November 27, 1883. Relieved from temporary duty at New York, and placed on waiting orders, December 31, 1883.

Fisher, J. C., Passed Assistant Surgeon. When relieved by Assistant Surgeon Banks to proceed to New York for duty, October 29, 1883. Granted leave of absence for thirty days, November 28, 1883.

Goldsborough, C. B., Passed Assistant Surgeon. Granted leaves of absence for thirty-two days on account of sickness, October 12, October 20, and November 1, 1883.

Irwin, Fairfax, Passed Assistant Surgeon. To proceed to Norfolk, Va., and assume charge of the service, relieving Assistant Surgeon Glennan, October 16, 1883.

Mead, F. W., Passed Assistant Surgeon. To proceed to Portland, Oregon, inspect the service, and report the condition of Assistant Surgeon Devan, December 5, 1883. Return to station, Port Townsend, Washington Territory, December 18, 1883.

Cook, H. P., Passed Assistant Surgeon. To proceed to Charleston, S. C., for duty, November 27, 1883.

Banks, C. E., Assistant Surgeon. Detailed for temporary duty at Georgetown, D. C., October 11, 1883. Granted leave of absence for thirty days, October 12, 1883.

Bennett, P. H., Assistant Surgeon. Placed on waiting orders, December 15, 1883. Granted leave of absence for thirty days, December 22, 1883. Upon expiration of leave of absence to proceed to Detroit, Michigan, for duty, December 29, 1883.

Peckham, C. T., Assistant Surgeon. To proceed to Wilmington, N. C., and assume charge of the service, relieving Passed Assistant Surgeon Irwin, October 16, 1883.

Devan, S. C., Assistant Surgeon. Granted leaves of absence for ninety-five days, on account of injury and sickness resulting therefrom, November 15, December 5 and 22, 1883.

Bevan, A. D., Assistant Surgeon. To proceed to Portland, Oregon, and assume charge of the service, December 29, 1883.

Glennan, A. H., Assistant Surgeon. To proceed to New Orleans, La., for duty, October 17, 1883.

Wadlin, Eugene, Assistant Surgeon. To proceed to Mobile, Ala., for temporary duty, October 11, 1883. To proceed to Galveston, Texas, for temporary duty, November 17, 1883.

PROMOTIONS.

Benson, J. A., Passed Assistant Surgeon. Promoted and appointed Passed Assistant Surgeon by the Secretary of the Treasury, from October 1, 1883, October 4, 1883.

Banks, C. E., Passed Assistant Surgeon. Promoted and appointed Passed Assistant Surgeon, by the Secretary of the Treasury, from November 1, 1883, November 6, 1883.

Beer Drinking.

From *Good Health* we learn that the president of the Connecticut Mutual Life Insurance Company has for years been investigating the relation of beer drinking to longevity. His object was that he might solve the problem whether beer promotes vitality or otherwise; in other words, to know whether beer-drinkers are desirable risks to a life insurance company. We give his conclusions. He declared, as the result of a series of observations carried on among a selected group of persons who were habitual drinkers of beer, that although for two or three years there was nothing remarkable, yet presently death began to strike, and then the mortality became astounding and uniform in its manifestations. There was no mistaking it; the history was almost invariable; robust, apparent health, full muscles, a fair outside, increasing weight, florid faces; then a touch of cold, or a sniff of malaria, and instantly some acute disease, with almost invariable typhoid symptoms, was in violent action, and ten days or less ended it.

It was as if the system had been kept fair on the outside, while within it was eaten to the shell; and at the first touch of disease there was utter collapse; every fiber was poisoned and weak. And this, in its main features, varying in degree, has been his observation in beer-drinking everywhere. It is peculiarly deceptive at first; it is thoroughly destructive at the last.

Dangers to the Public Health from the Erection of High Apartment Houses.

Dr. Vanderpool told the New York County Medical Society that the sanitary objections to these enormously high buildings affected both the inmates of them and the occupants of adjoining property. Among those affecting the inmates were the impossibility of complete isolation in case of the outbreak of contagious disease, the cutting off of the first three floors from sunlight, and the danger of miasm being conducted to the upper floors by means of the air-shafts employed for ventilation. Among the dangers to the occu-

pants of neighboring property were the rendering of the streets damp and unhealthy by excluding the sun from them, and the establishment of new currents of air, which were liable to cause smoky chimneys and interfere with the sewer ventilation of houses of the ordinary height.

Gas from Sawdust.

An excellent use has been found for the enormous quantity of sawdust annually made in the lumber regions of our country. From the *Popular Science News* for February, 1884, we learn that illuminating gas is made from it. Any kind of sawdust can be used; but that from resinous woods is preferable, and affords a larger yield of gas. From twenty thousand to thirty thousand cubic feet of gas are obtained from a net ton of fuel. The wood-gas has the advantage of containing no sulphur, is more easily purified than coal-gas, and is said to be fully as good, while it is less expensive. The ordinary burners are used for wood-gas. Mill-owners can construct chemical works to make their own gas.

Adulterations.

The question has been often asked whether the adulteration of food articles is injurious to health, and it is gratifying to note in an article by Dr. William K. Newton, read before the American Public Health Association, "that the simple articles in every-day use are never adulterated with injurious substances, and the evidence thus far offered indorses the statement made in the first part of this paper, that adulteration is a sin against the pocket, and extremely rarely against health."

Death of Dr. Reichert.

Dr. Reichert, late Professor of Anatomy in the University of Berlin, died recently at the age of seventy-three. He was appointed to the professorship in 1858, on the death of Johannes Müller, when the Chair of Anatomy and Physiology, held by that distinguished physiologist, was divided; the department of physiology being assigned to Dr. DuBois-Reymond. A few months ago Dr. Reichert retired from his chair, and was succeeded by Dr. Waldeyer, of Strasburg.

Philadelphia Neurological Society.

This Society was organized on Monday, January 28, 1884, when the following officers were elected: *President*.—Dr. S. Weir Mitchell.

Vice Presidents.—Drs. C. K. Mills and T. N. Kerlin.

Secretary and Treasurer.—Dr. James Hendrie Lloyd.

Council.—Drs. S. Preston Jones, Wharton Sinkler, and J. T. Eskridge.

A Reception to Professor Parvin.

The Alumni Association of the Jefferson Medical College gave a reception in honor of Professor Theophilus Parvin, M. D., LL. D., on Monday evening, January 28, 1884, at the St. George Hotel, Philadelphia. A large number of representative medical gentlemen were present.

The Influence of Pavements in Disease.

We note from the *Lyon Med.* that a condition of oedema of the legs has appeared among workmen in the factories since the removal of wooden floors. Bricks seem to make the least injurious pavement, asphalt the worst, and, in order, come cement and stone.

Bismarck and His Medical Attendant.

The *Med. Record* says that Bismarck has made his medical attendant, Dr. Schweninger, a "Professor" unattached. He has no lectures to deliver, students to teach, or chair to occupy, but is simply Professor of the Anatomy, Physiology, and Pathology of Bismarck.

Personal.

—On the evening of January 28, a very pleasant reception was given by the physicians of Philadelphia to Dr. Theophilus Parvin, the recently elected Professor of Obstetrics of the Jefferson Medical College.

Items.

—According to the *Deutsche Medicinal Zeitung*, the widow of Prof. Ball, who is a daughter of Traube, has been made a doctor of medicine in Rome.

—Prof. H. Newall Martin, of the Johns Hopkins University, of Baltimore, has been appointed the next Croonian lecturer of the Royal Society of London.

—In the *Maryland Med. Jour.*, January 19, 1884, Dr. Latimer relates a case of puerperal convulsions cured by hypodermic injections of veratrum viride.

—"Boss, hab you got any dem confound confortic pills?" "Yes. Do you want them plain or coated?" "Dunno. I want dem ones dat's whitewashed." He got 'em.

—The British Medical Association object to the compulsory notification of infectious diseases by the physician, preferring to have this obligation placed upon the householder.

—The palace of the ex-Empress Eugenie at Marseilles, which she was obliged to give back to the city, has been turned into a medical school for the training of army medical officers and others.

—Sixty bushels of pamphlets, advertising a patent medicine, were received in the Boston post office recently, and were found, on examination, to contain also a circular advertising a Kansas lottery.

—The laws of Kansas do not allow the prescription of liquors by physicians except under circumstances of extreme need, and the physician has to take the risk of a jury's deciding against him on this point.

—A curious suit has been entered for trial in Washington. A gentleman there has sued his family physician, asking \$1,000 damages, for malpractice, the cause being that the latter failed to prevent the spread of a contagious disease in the family.

—The Regents of the University of the State of New York, on January 11, 1884, refused to grant a charter to the United States College of Medicine and Surgery of New York City.

—The Swedish Government intend to establish a botanico-physiological station in the north of Sweden, for the study of the flora and the diseases of the crops in that part of the country.

—Mr. Huxley says the body is a machine of the nature of an army, each cell is a soldier, each organ a brigade, the central nervous system headquarters and field telegraph, the alimentary and circulating system the commissariat.

—According to the *Med. Times and Gaz.*, Dr. Wilson Fox has publicly recanted his views as to the communicability of tubercle by inoculation, holding now the view of Koch and the German school, that it can only be produced from tubercle.

—Dr. Arning, late assistant to Professor Neisser, of Breslau, has been sent to Honolulu, in order to study the pathology of leprosy, and especially to investigate the question of the rôle played by the bacillus of leprosy in causing the disease.

—A case of death from the inhalation of ether occurred at a clinic at Bellevue Hospital recently. The patient was a boy with apparently sound lungs and heart. He was under ether for about an hour and a half, when he suddenly ceased to breathe, and all efforts at resuscitation failed.

—The *Jour. de Med. de Paris* says that decoction of quassia, applied to mosquito bites, constitutes an excellent remedy for the relief of the itching and irritation. When applied to the exposed portions of the body, it is also a preservative against the attacks of these very disagreeable and annoying insects.

—The *American Druggist* says that an Indiana court granted a divorce upon the prayer of a woman, the wife of a physician doing a large and lucrative business, based upon his refusal to give up his night practice. The presiding judge praised the progressive liberality of the laws which permitted the release.

—The wife of a postmaster at Serampore, India, a Brahmin lady of good social position, has recently entered the Woman's Medical College in this city, with a view to fit herself for aiding in the elevation of her sex in her own land. By such an act she violates the regulations of caste, and suffers social ostracism.

—The amount of carbonic acid generated by lights is thus represented: Electric lights, none; argand gas-burner, .46; flat-flame petroleum, .95; colza-oil light, 1; paraffine candle, 1.22, and tallow candle, 1.45. It has been remarked that the tallow candle, the oldest of these artificial lights, is not only the hottest, but the most unhealthy.

—The *American Journal of Otology* reports the following: "A doctor of extensive practice suffered from a crackling noise every night just after going to bed. He happened to mention his sufferings to one of his lady patients, who told him of a case she knew where the noise was found to be due to maggots in the pillow. The doctor examined his own pillow when he got home and found plenty of maggots, the pillow having gone far toward decay. A new pillow cured him."

QUERIES AND REPLIES.

EDS. MED. AND SURG. REP.—

Will you kindly give information as to the better way by which the odor of iodoform may be disguised? Tonka bean is not effectual.

R. A. R.

Mass.

EDS. MED. AND SURG. REP.

How do you reconcile your first answer to T. J. H., in December 29th number of *REPORTER*, with Art. I.—Duties of the Profession to the Public, Sec. I.—"also be ever ready to give counsel to the public, etc., etc., on subjects of medical police, etc., etc.," Sec. III, Ib. "Professional brotherhood and certain public duties referred to in the first section, etc., should always be recognized as presenting valid claims for gratuitous services."

How your second answer, with "Duties of physicians to each other, and to the profession at large," Art. I., Sec. III., Dr. T. J. H. referred in his query to a hand-bill posted outside of the physician's office, on the public square, at the bottom of a stairway leading to same.

T. J. H.

Ans.—1. We do not understand the words of the Code to imply that a physician should give gratuitous advice to any corporate body, municipality, or public board. They are able, and they should be willing, to pay for the time and counsel of a medical man, just as they would for the time and counsel of a lawyer. The "public" referred to is the general public, not organized official bodies.

2. Posting a notice that a physician has pure vaccine virus, said notice being on his office, or on the door leading to his office, does not seem to us indecorous or irregular. We must even confess that to our mind putting such a notice in the newspapers, if it was plainly and properly worded, would not be amiss, and would do more good than harm.

MARRIAGES.

DETWILER—THOMAS.—In Milford, N. J., January 2, 1884, by the Rev. Isaac M. Patterson, assisted by Rev. P. O. Studdiford, of Lambertville, T. Craig Detwiler, M. D., of Williamsport, Pa., and Frances, daughter of Edward Thomas, Esq., of Milford.

EWING—BAXTER.—By the Rev. A. Donaldson, D. D., December 20, 1883, Dr. C. M. Ewing and Miss Artie Baxter, both of Olivet, Armstrong county, Pa.

HETRICK—EDWARDS.—At the residence of the bride's father, December 25, 1883, Dr. J. S. Hetrick, of Venedocia, Van Wert county, O., and Miss Kate Edwards, of Pomeroy, Ohio.

PALMER—CALDWELL.—At the residence of Mr. Wm. R. Fox, Louisville, Ky., January 3, 1884, Dr. Marshall Key Palmer, of Lebanon, Ky., and Miss Ella Caldwell, of Danville, Ky.

SCHWENK—VAN CAMP.—In Philadelphia, on the 25th of December, 1883, by the Rev. N. I. Rubinkam, Dr. C. S. Schwenk and Miss Annie L. Van Camp, of Trenton.

MELHORN—RICE.—At the residence of the bride's parents, Camden, Indiana, on New Year's Eve, by the Rev. D. H. Snowden, M. D., Dr. D. H. Melhorn, of New Chester, Pa., and Miss Minerva Rosalie Rice, only daughter of Col. Rice.

CLARK—SWIFT.—In Eugene City, Oregon, on Christmas Eve, 1883, by the Rev. E. R. Geary, Dr. Edward Geary Clark and Frankie Swift.

LOUTHAN—BURROWS.—At Cherokee, Ia., December 13, 1883, by the Rev. J. B. Chase, J. M. Louthan, M. D., and Miss Louie Burrows.

DEATHS.

MERRILL.—In Boston, Mass., January 14, 1884, Dr. John W. Merrill, Jr., son of Rev. J. W. Merrill, D. D., aged thirty-four years.

MRAVLAV.—At Elizabeth, N. J., January 25, 1884, Lucy Allen G. Mravlag, M. D., wife of Victor Mravlag, M. D.

PROOF THAT HUMAN MILK CONTAINS ONLY ABOUT ONE PER CENT. OF CASEIN; WITH REMARKS UPON INFANT FEEDING.

BY ARTHUR V. MEIGS, M. D.,

Physician to the Pennsylvania Hospital and Children's
Hospital, of Philadelphia.

Read before the Philadelphia County Medical Society.

You must give me your indulgence for bringing before you a subject necessarily somewhat dry in its details, but its great importance must be my justification. Nearly two years ago, I had the pleasure of reading here a paper upon "Milk Analysis," when I described the method I had worked out, and briefly detailed my results. The main conclusion was that human milk never contains more than about one per cent. of casein, and this observation I then claimed to be a new one, and very important, as showing how we should feed infants so unfortunate as to be deprived of their natural sustenance. A year or more ago, I delivered a lecture to the class at the Pennsylvania Hospital, which was subsequently published in the *Medical News* of November 4, 1882, in which I described a plan of feeding deduced from the results of numerous experiments and analyses. This evening, I wish, first, to offer proof that the results arrived at by the method of analysis are correct, and, second, to make some suggestions about the proper method of infant feeding.

Although many chemists have made analyses of human milk, and a great variety of divergent re-

sults have been attained by different methods, there has as yet been no proof offered of the correctness of any of them. This constitutes an important missing link in any attempt to place the question of the composition of milk upon a settled basis; and if a method of analysis is ever devised that will give results which shall be universally accepted, and stand the test of time, the accuracy and correctness of the method must be susceptible of proof—simple, scientific, and incontrovertible proof. Some proof of the correctness of the analyses described here two years ago will now be attempted.

No one disputes that in ether, chemists have a perfect solvent for fat, which, when properly applied in milk analysis, extracts it all. The fat when separated can be seen, and the eye tells positively that it is fat.

With regard to the water, it is equally certain that by the evaporation process its amount can be accurately estimated. This statement is made with the knowledge that there may be with the water some slight traces of other fluids—alcohol, for instance, and perhaps other volatile liquids; but these must be in such minute quantity that they need not be taken into consideration, and for the present the liquid portion of milk may be spoken of as the water. It is equally certain that in incineration, properly performed, there exists an easy and correct method of determining the amount of inorganic matter. In the future, of course, there may be perfected some way of estimating the salts in milk, by extracting from the liquid milk, or from the solid residue left after evaporation, and this may show them to exist in larger quantity than the present method of incin-

eration leads to believe; but the possible error introduced in this way must be very small, and does not invalidate the general facts stated. That the existing estimates of the water, fat, and inorganic matter are correct, is further proved by the fact that there is no difference of opinion in regard to their amounts. Examination of the analyses of different chemists shows an almost exact uniformity of conclusion with regard to the relative quantities of the above-mentioned substances.

When the estimates of the casein and sugar, however, are considered, the widest divergence of view is discovered in the conclusions as to the amounts existing in human milk. In regard to cows' milk, chemists all arrive at nearly uniform conclusions. The casein in human milk is estimated by Dolan and Wood, in one of their analyses, at 7.005 per cent., Vernois and Becquerel give it as 3.924 per cent., and Henri and Chevalier as 1.52 per cent., while my own experiments lead me to conclude that there is about 1 per cent. Now the fact is a striking one, that if in any of these analyses the sugar and casein amounts be added together, the sums are found to be in each instance nearly the same. The subjoined table shows this to be the case.

	Vernois and Becquerel.	Simon . . .	Henri and Chevalier.	Dolan and Wood . .	Haidlen . .	L'Héritier .	Doyère . .	Clemm . .	Tidy . . .	Meigs . . .	Payen . . .	Quevenne .	Regnault . .
Casein	3.924	3.43	1.52	7.005	3.1	1.30	.85	3.533	3.533	1.046	.215	1.05	3.9
Sugar	4.364	4.82	6.50	1.921	4.3	7.80	7.31	4.118	4.624	7.407	8.805	7.31	4.9
Total	8.288	8.25	8.02	8.926	7.4	9.10	8.16	7.651	8.157	8.453	9.020	8.36	8.8

The estimates of Haidlen, L'Héritier, Doyère, and Clemm, are taken from a table in the *Physiologische Chemie* of Gornp-Besanez; those of Vernois and Becquerel, Payen and Regnault, are taken from one in the *Traité de Chimie Pathologique* par Becquerel et Rodier; but the others are from the original sources. A complete estimate of all the constituents is not attempted in the analysis of Quevenne; and under the head which is called casein in the table is included albumen (*matière albumineuse précipitée par l'alcool*); under that of sugar are included also extractive matters (*lactine et matières extractives*).

The table also shows that, in each instance where the casein amount is large, the sugar is small; and *vice versa*—that where the casein amount is small, that of sugar is large.

It has been already said that as regards the analysis of human milk, all observers are agreed as to the proportions of the water, fat, and ash; it is now further evident, from the table, that all agree as to the quantities of casein and sugar taken collectively, and that only when the separation of the two is attempted does there exist any difference of opinion. The separation of the casein from the sugar, therefore, is the difficult part of milk analysis, for in regard to this alone

is there any difference of opinion. In this portion of milk analysis, then, is reached the stumbling block; and it alone requires any explanation, for the rest is universally conceded, and cannot, therefore, but be considered as already placed upon a scientifically exact basis.

There are but two possible explanations of the different results arrived at by various investigators; one, that human milk is as variable a substance in regard to the amounts of casein and sugar contained, as the different analyses would lead to believe; and the other, that the methods of the majority of chemists have been faulty and their conclusions incorrect. That the second of these two explanations is the correct one, does not admit of doubt. Wanklyn says that cows' milk is a substance exhibiting great uniformity of composition, and what he says of cows' milk is also probably true of human milk. There is no reason to expect that it would vary so much in regard to the proportions of casein and sugar, when cows' milk exhibits such uniformity of composition in these respects. It may, by analogy, be fairly argued that human milk is very unlikely to be so variable as published analyses would seem to show. The proof of this, however, lies

in showing, by examination of a large number of specimens, that human milk always contains a large amount of sugar (say 7 per cent.), and therefore by exclusion it cannot contain the great amount of casein it is usually credited with, for all observers agree as to the sum of the amounts of the two substances.

The existence of this large amount of sugar in human milk I have endeavored to demonstrate by experimenting as to how much could be obtained in the crystalline form from any fixed quantity, and then, by applying the same process to cows' milk, to find out whether an equal or, as should be the case if my already published original an-

alyses are correct, only a less quantity of sugar will take the crystalline form.

An experiment was made as follows: 10 cc. of human milk, which had already, by the process described in my previous paper, been found to contain 7.224 per cent. of sugar, was, as usual, agitated with ether and alcohol, and the fat removed. After the removal of the fat the remaining portion was carefully washed into a dish, and in the water-bath, at a temperature of 70° to 80° C., evaporated until only about 10 cc. of fluid remained; upon this was poured a mixture of 25 cc. of water with 25 cc. of alcohol, and the whole allowed to stand over night. By morning a precipitate had formed and settled to the bottom of the vessel; this was thrown upon a filter and washed with a mixture of equal parts of boiling alcohol and water. The filtrate was again reduced in the water-bath, at a temperature of 70° to 80° C., to about 10 cc., and then 75 cc. of absolute alcohol added. This caused again the formation of a slight precipitate, which was allowed to thoroughly settle to the bottom, when the perfectly clear fluid above was poured off into a dish, care being taken that none of the precipitate passed over with the clear fluid. This liquid was allowed to evaporate, without heat, in an open dish of known weight, and there remained finally only crystalline milk-sugar, with a very minute amount of the inorganic material. The 10 cc. of milk thus treated, yielded 659 milligrammes of sugar dry at 100° C. This milk had been previously ascertained to contain 738 milligrammes of sugar to each 10 cc., which made its percentage of sugar 7.224, as already stated. These figures are sufficiently nearly parallel to prove the point, for by the method of crystallization described, it was not expected that all the sugar present would be obtained in the crystalline form, some of it being necessarily precipitated with the casein in the course of the manipulations with alcohol; but only to obtain it pure, and in sufficient quantity to prove that the sugar existed in the milk in the large quantity shown by the analysis, and therefore necessarily by exclusion, the existence of only the small amount of casein. The demonstration thus obtained seems incontrovertible, for when the existence of the large amount of sugar is shown, it follows as a necessary corollary that there can be only the small amount of casein, and therefore the existence of the small amount of casein in human milk is proved.

As a means of further proving that the sugar obtained by crystallization, as described, was en-

tirely free from any traces of casein, it was tested for me by Mr. J. K. Hecker, the apothecary of the Pennsylvania Hospital, by the Nessler test described by Wanklyn and Chapman (*Water Analysis*, by J. Alfred Wanklyn and Ernest Theophron Chapman, London, 1876, p. 25). This test decomposes the casein and forms ammonia from the nitrogen. When the crystalline sugar was subjected to its action, it showed it to be practically free from casein.

Cows' milk, when subjected to the same process of precipitation of the casein by alcohol, after the removal of the fat, yielded only about 4 or 5 per cent. of crystalline sugar. The manipulations were not carried out with the care that was taken when human milk was examined, for there is no dispute as to the amount of sugar in cows' milk; the experiment was therefore made merely to afford confirmatory evidence of what was shown by that upon the human milk. For if only a little more than 4 per cent. of sugar existed in human milk, as is claimed by Vernois and Becquerel, and others, and this being the quantity universally conceded to exist in cow's milk, then when both were subjected to the action of the same reagents, the same amount only of crystalline sugar should be yielded. This, however, was not the case.

One of the strongest proofs of the correctness of the estimates of fat in milk is afforded by the fact that after it has been separated, it can be seen, and the eye tells that it is fat. When sugar is crystallized, and can be seen and felt, and examined with the microscope or a magnifying-glass, and the characteristically shaped crystals of milk-sugar are seen, the fact that it is sugar, and nothing else, becomes self-evident.

To test still further the accuracy of the method described in my former paper upon milk analysis, I carefully analyzed a specimen of human milk, and found it contained the different proximate constituents in about the usual quantities. Then I separated from a further portion of the milk, taken at the same time and under exactly parallel circumstances, fresh portions of the casein and sugar, which I gave to Mr. Hecker, to test their purity; the sugar to be subjected to the Nessler test, to discover if it contained any casein, and the casein to be subjected to the action of Fehling's test, to find whether or not it was free from all traces of sugar. The casein entirely failed to produce any effect upon the copper solution, thus showing that it was free from sugar, while if a small portion of the sugar was added to the solution, the characteristic reduction of the

copper at once took place. When the sugar was subjected to the Nessler test, .05 grammes being introduced into the retort when the decomposing materials were ready, it almost entirely failed to react, showing no more change than would be accounted for by the distilled water which had been used to prepare the sugar. This distilled water must have contained traces of organic matter, for when it was subjected to the test, it showed slight traces of ammonia. The test is so delicate, that it is only by the greatest care and nicety in preparing the materials that they can be had perfectly free from all nitrogenized materials. The conclusion was that the sugars—both that prepared by the ordinary process advised for analytic purposes, and that obtained by crystallization—were, practically speaking, free from casein.

If, then, it has been shown that human milk contains approximately 87.1 per cent. of water, 4.2 per cent. of fat, 7.4 per cent. of sugar and 0.1 per cent. of inorganic matter, the proof that it contains, not 3 or 4 per cent. of casein, as is commonly taught, but only about 1 per cent., is complete.

It may seem bold to make statements directly contradictory of the correctness of many of the usually accepted standards, but it is done with the full knowledge that it is liable to contradiction. There is an article on "Infant Foods," by Prof. Albert R. Leeds, in the *Transactions of the College of Physicians*, third series, vol. vi., Philadelphia, 1883, in which he gives results quite different from my own; but as he gives no account of the methods he pursued, any criticism of his results is at the present time impossible.

In the endeavor to find a food which shall be the best for infants who have to be hand-fed, there are two considerations, either of which might be selected as the basis from which to start. In the first place, the desired goal might be attained by making trial of all sorts of foods; and these being put to the test of experience, the good would be retained and the bad gradually weeded out, until at last perhaps the most suitable would be found, and slowly introduced. On the other hand, the desired end might be attained by trying to produce a food which should be, as nearly as possible, like what nature has provided for the infant. Many trials have been made in the past by both these methods, but to the second one justice has never been done; for, if my conclusions are correct, a proper understanding of the composition of human milk, from which to start, has been wanting.

A clear understanding being now had of its proximate constituents, and the proportions in which they exist, it is possible more intelligently to set about finding how the same elements may be had, and mixed together to make an artificial food like human milk. Cow's milk is almost universally the basis of the foods used, in this country at least.

The artificial food which I shall presently recommend is the outcome of a study of the subject from both of the standpoints suggested, and its advantages are demonstrable. Upon theoretical grounds, it is what a food for infants should be; for analysis of human milk and cows' milk has shown what is their composition, and in the artificial food the elements have been introduced in the same proportions as they exist in human milk. Experience has for many years past been tending in the direction of proving such a food to be what is needed; for, while almost innumerable manufactured infant foods of every variety have been introduced, and have often for a time been thought all that could be desired, they have all, one after another, fallen into disuse and been forgotten; but the use of cows' milk continues to hold its own, and in civilized countries is employed ten times more than all the manufactured foods together. The question, however, remains of how to use it, and the various methods suggested have been almost as numerous as the physicians who have advised them. For a long time the great majority of writers upon infant diseases and diet have recommended that cows' milk should be diluted before giving it to young infants; and this, they all agree, is because it contains too much casein, which causes a curd that only infants of the strongest digestion can with safety assimilate.

The weight of testimony that cows' milk contains much more casein than human milk, is so great that it is astonishing how almost universally the analyses of human milk of Vernois and Becquerel, and of those who have arrived at like conclusions, have been accepted and given credence, despite the fact that the evidence of the senses of every one who has examined into the matter is diametrically opposed to such acceptance. Although, as already said, the weight of authority has long been in favor of the use of diluted milk, still there have always been those who recommended it to be used pure. Of later years more and more has been said and written upon the advantages to be derived from the use of cream, or diluted cream. Dr. J. Forsyth Meigs, who was a well-known authority upon the com-

plaints of children, for years used with great success a mixture of equal parts of milk, cream, lime-water, and a weak arrowroot-water, with a little sugar. Cream mixed with whey, to increase the sugar and lessen the amount of casein, has been recommended. Biedert (*Virchow's Archiv*, Band 60, 1874,) has written an article, and concludes that the best food is cream and water, one part to four, with fifteen grammes of milk-sugar to the half litre of the mixture, the strength of this to be gradually increased. Biedert made many experiments comparing the relative coagulability of human and cows' milk, and again the digestibility of the coagulum; as can therefore be presupposed, his experiments turned mainly upon the two kinds of casein and their differences. He concludes that "there are two important points in which human and cows' milk are unlike: first, in the different amounts of casein contained; and second, in the absolute chemical differences of the two sorts of casein. The first of these considerations would be of but little importance, however, if the analyses which place the average of casein in human milk at four per cent. are correct; its importance, on the other hand, would be very great if it usually contains—as I, in agreement with Vierordt's view, believe—only from two to two and one-half per cent. I think many further analyses are necessary to establish absolutely this point. Even if this view is accepted, however, dilution of cows' milk with equal or more parts of water is not sufficient to remove the differences. It is well known that such a dilution does not remove all the disadvantages which arise in the use of cows' milk, and my clinical experience has taught me that even dilution with two parts of water does not attain the desired end; and the explanation of this positive irremovable difference is to be found in the important chemical differences which exist, the casein of cows' milk coagulating so much more easily, and the coagulum being so much more firm than is the case with the casein of human milk; and, on the other hand, the coagulum being so much more difficult of solution or digestion.

"Until we succeed in actually making the casein of cows' milk identical with that of human milk, it will be necessary to give infants only so much of it as they can digest (no matter how great the necessary dilution may be), and to make up to them with carbo-hydrates (fat and milk-sugar), the lack of albuminates in the food." He further says: "After numerous experiments, I have come to the conclusion that the amount of cow casein which an infant's food should contain

is one per cent. The fat and sugar in cows' milk appear to be as easily digested, and in no wise different from those contained in human milk. If, therefore, one-eighth of a litre of sweet cream (which, according to Hoppe, contains nine and one-half per cent. of fat, three per cent. of sugar, and four per cent. of casein) is diluted with three-eighths of a litre of water, which has been previously boiled, and milk-sugar is added in the proportion of fifteen grammes to the half litre, the desired cream mixture is produced, and contains one per cent. of casein, 2.4 per cent. of fat, and 3.6 per cent. of milk-sugar, which will be found, under all circumstances, to be well borne, and is a sufficiently nourishing food." The greatest part of Biedert's admirable article consists of a detail of experiments made of treating cows' and human milk, and the caseins obtained from both sorts, with a variety of reagents, and observing the different relative effects produced. His conclusion is that "the pure casein of human milk is, in both its physical and chemical nature, different from that of cows' milk." The casein of cows' milk, when isolated, has always an acid reaction; while, on the contrary, that obtained from human milk is always alkaline. If human casein is treated in a certain way with acid, there is produced an "acid modification of human casein," which has many points of resemblance with ordinary cow casein; on the other hand, by treating cow casein with alkali, a substance is produced which shows, with many reagents, identically the same changes that are, by like treatment, produced in human milk. After careful examination of these two substances, however, Biedert concludes that "cow casein treated with alkali is, in many respects, much more like human casein than the original cow casein, yet it always shows unmistakable differences." Although he makes a strong case, and there are many reasons in favor of accepting his conclusions, yet, in the present state of knowledge of casein, the difference cannot be considered as absolutely demonstrated.

(To be continued.)

A CASE OF FRACTURE OF FEMUR, WITH EXCESSIVE LACERATION OF THIGH, TREATED SUCCESSFULLY, WITH POSSIBLY SOME NOVEL FEATURES.

BY GEORGE W. JOHNSON, M. D.

Of Savanna, Ills.

Acting as surgeon of the C. M. and St. P. R. R.,
I was called November 3, 1883, to attend a case of

railroad injury, in the person of Edward P., a robust man about 25 years of age,

I learned the following particulars of the accident. On attempting to make a coupling, his foot was caught by the guard-rail, and he was thrown in such a manner that the left thigh lay across the track, about its middle; a signal being quickly given, the engineer reversed the engine, which brought the train, which was backing and moving slowly, to so sudden a stop that but one wheel passed over the leg, but the reversal suddenly jerked the wheel back again over the limb at about the same place.

When seen immediately after the accident, the man was suffering severely from shock. On examination of the leg, I found a laceration of the integuments on the outer and back part of the

thigh, commencing at a point a little below and to the outer side of the knee, and extending the entire length of the thigh, ending at the sub-gluteal crease, the upper two-thirds of the rent being directly posterior.

The laceration extended through the integuments and cellular tissue, and at about the middle of the thigh, the superficial flexor muscles were torn entirely across, their ends hanging from the wound.

The femur was fractured, with some comminution at about the junction of the lower with the middle third; leg everted, and two inches of shortening.

The skin on the anterior aspect of the thigh, bore two broad marks as of intense compression, though but slight breaking of the skin had occurred. A tear was also found extending from just in front of the anus, up the side of the scrotum, nearly to Poupart's ligament.

That more extensive lacerations of the limb had not taken place, seemed owing to the fact that

the man was very heavily clad in strong outer and under-clothing, and to the slow motion of the car.

Under an anæsthetic, I made careful examination; the man begging me previously to spare him his leg, even at an increase of risk to his life.

On introducing my fingers into the wound, I sought for the communication with the fractured bone, which I felt sure existed, but I could detect none.

Circulation being good in the lower leg, and sensibility fair, I determined to make an attempt to save the member, even if in a very imperfect condition.

The external wound, which was gaping widely, was closed with sutures, the leg was placed in a straight position upon pillows, and carbolated water dressings applied. Considerable traumatic fever was present during the first few days, and much swelling, especially at the knee.

The water-dressings were continued for ten days, the patient being rolled upon his side for their application, and the leg supported by assistants; but although conducted with the utmost care, at each dressing quite a considerable amount of displacement occurred at the seat of fracture.

To arrange some fixed apparatus for the fracture, which at the same time would permit the attention demanded by the wound, now became a necessity.

After the sutures and some sloughs had separated, leaving the wound clean, I applied extension by adhesive straps, weight, and pulley. Counter extension being secured by the weight of the body, the foot of the bed being raised six inches, Ahl's posterior tibial splint was applied to the lower leg, swinging the same by cords to pulley in the ceiling. I now made a posterior thigh-splint of *sheet zinc*, long and wide enough to embrace the entire back of the thigh, perforated with holes about one-eighth inch in diameter as thickly as was consistent with strength, laid a covering of carbolized gauze over internal surface, and applied the splint thus prepared to the thigh; the raw surface lying directly upon the zinc, only covered by the gauze. Two wire bails were now put across over the thigh, attached to the splint on either side; to these I attached a cord which passed over a pulley in the ceiling. I now, by tightening both my suspending cords, could elevate the entire leg free from the bed, and lower at pleasure, the leg being still kept in line without removal of the extension, as the pulley was some two feet removed from the foot, thus allowing considerable latitude of motion.

The daily dressing consisted of a pillow of absorbent cotton, covered with carbolized gauze, placed under the metallic splint, and receiving the drainage which passed freely through the perforations, the gauze-lining of the splint serving to prevent the protrusion of fungus granulations.

After dressing, the leg was lowered nearly, but not quite, to the bed, the Ahl thigh-pieces were applied to the sides and front of the thigh; a long outside splint reaching to the axilla and below the foot, with a wooden pin at the edge of the lower end passing through a bar fastened across the foot of the bed, was now bound fast to the leg at ankle, knee, upper part of thigh, and by body band, serving to keep all firm and immovable.

For extension weight I at no time used over eight pounds, the weight required probably being less on account of section of some of the muscles.

Some sloughing of the skin on front of thigh took place, but wound soon healed, as did also the wound along the perineum.

My daily routine now consisted of loosening the long splint, laying it aside, raising the leg with the aid of an assistant sufficiently high to allow of the removal of the soiled pillow, and the substitution of a fresh one, lower, and reapply the long splint.

The result has exceeded my most sanguine expectations; the zinc proved soothing to the wound, the discharge, profuse at first, gradually lessened, and at the end of the sixth week after the application of the splint, bony union was found to have taken place, and after waiting for additional security two weeks longer, the apparatus was removed, the wound examined and found healthy, fully one-half its length being healed, and healthy granulations, even with the surrounding skin, covering the remainder, with the process of cicatrization progressing rapidly. Two weeks have now elapsed since removal of the splints, and the wound, which is dressed with oxide of zinc ointment, is healing slowly, but kindly. The patient is now able to sit up in a chair, and begin the use of crutches.

On the most careful measurement, no shortening can be detected.

The bed used was improvised from a canvas-covered cot, a trap being cut; and a cushioned cross-board below, with loose hinges at one end, and hooks at the other, served to close the opening when not in use.

I am aware that our best authors advise amputation in cases of this kind, and it may have been a very dangerous experiment to make; but as the case has progressed so happily thus far toward a

cure, and believing the use of the *zinc splint in direct contact with the large wound* is somewhat novel, I will submit the report of the case for what it is worth.

ODONTO-PERIOSTEAL TUMOR SIMULATING PULP-FUNGOID.

BY JOHN S. SMITH, D. D. S.,
Of Lancaster, Pa.

Miss K., a lady aged 21 years, presented herself for treatment October 12, 1883.

She had long suffered from neuralgia, confined principally to the right side of the face, and particularly along the course of the inferior maxillary nerve.

Examination revealed caries of the teeth. Several had died, and there were suppurating pulps in others which were exposed and congested.

When making the examination, my attention was arrested by seeing a tumor the size of a large bean, which completely filled a carious cavity of the first permanent molar tooth on the lower jaw. The crown of the tooth was broken in places nearly to the line of the gum, and the tumor overlapped the rough edges. This caused the growth to present an angry and inflamed appearance. There was considerable pain when pressure was made to the alveolar process corresponding to the tooth.

The growth was over three years old. It had not been troublesome until within the past year, during which time it had steadily grown worse, and this, and the painful condition of her other teeth already mentioned, drove the lady to seek surgical aid.

Diagnosis.—What is this growth? To all appearance it looks not unlike the pulp-fungus which has its origin in the bulbous portion of the tooth-pulp, and could be readily mistaken for a fungus of that expression. In the latter condition the removal of the tooth would be alone sufficient for a cure. The removal of the tooth would also remove the tumor.

We find by a careful examination with a probe that the fangs of the molar have been suppurated, and that the probe passes through into the alveoli; in fact, the fangs seem to be imbedded in the stroma. The fangs are loose, and portions of the alveolar process have been absorbed, so that the probe can readily be passed through it.

That the tumor is an outgrowth of that aspect of the odonto-alveolar membrane which adjoins the bone, is beyond doubt. The growth has passed through an opening between the roots of the tooth, making its appearance as above described.

We will therefore exclude pulp-fungus, which has its origin within the stroma of the dental pulp, which condition is perfectly innocent and benign in its nature.

The tumor was a form of epulide simulating, as location is concerned, the pulp-fungus, but a portion of the jaw was found implicated. It had involved it. In this case the simple removal of the tooth would not effect a cure.

Treatment.—The patient was placed in a Morrison dental chair, in a recumbent position, and etherized, Dr. D. R. Summy and Martin H. Musser assisting. The fangs were quickly removed. The engine burs were then made to complete the operation by cutting down that portion of the alveolus and bone involved; the gums were not cut away by the operation, but left intact on the outer and inner borders, this being preferable to removal, as it is a means of retaining the after dressing when found necessary. The hemorrhage was easily controlled with phenol sodique and tannic acid on cotton packed into the cavity.

In two weeks the wound was nicely granulated, and there has been no return of the tumor.

The other diseased teeth were subsequently treated and properly filled, and the neuralgic pains have entirely disappeared.

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL.

BY WILLIAM PEPPER, M. D., LL. D.,

One of the Physicians to the Hospital, and Professor of Clinical Medicine in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M. D.

The Treatment of Epilepsy—Lecture 2.

GENTLEMEN: You will remember that at the last lecture (see page 41) I brought before you two cases illustrating the graver forms of epilepsy, one coming on early in life, the other not making its appearance until adult age. In connection with these cases, I alluded to the following causal conditions, injuries to the head, a very frequent factor, and one the exact significance of which requires careful study to determine in individual cases. Heredity and the constitutional and spontaneous character of the disease is opposed to the secondary or organic character, a factor of greatest possible importance, both in treatment and prognosis; and the existence of peripheral irritation in any spot, a subject which requires close study in every case in order that we may avoid overlooking any such cause of reflex disturbance. I alluded particularly to lesions of the genitals, and especially to adherent prepuce and deranged conditions of the gastro-intestinal canal,

not only from worms and foreign matters, but also from slight chronic irritation of the mucous membrane.

Of course, in studying epilepsy, we separate epilepsy proper from those cases of epileptiform convulsions resulting from some serious lesion of the nerve centres, and leave entirely out of consideration these latter cases where there is some lesion of the brain, and recognize in epilepsy the expression of a tendency on the part of the nervous system to pass into a convulsive state from depressing or disturbing causes of a more or less powerful character.

I dwell upon the extreme importance of hygiene and suitable regimen in these cases, and I wish to speak a little further in regard to the influence of diet in cases of epilepsy, for it is one of the fundamental features of the scientific treatment of this disease. I know no disease in which it is more essential to pay attention to this point than it is in this; and it is the more important, because epileptics are, as a rule, voracious, hurried and careless eaters, often having morbid desires, and usually difficult to control. On the one hand, we have a disease which is undoubtedly attended with depression of the nervous system; and on the other hand, one in which a nourishing diet, consisting of such articles as minister to nerve force, is required. Fats and nitrogenous food are indicated, but it must always be remembered that the nervous system is so sensitive that the least peripheral irritation, and especially, I think, irritation of the stomach and intestines, will excite convulsions, or increase the tendency to them. The arrangement of the diet so that it will not, on the one hand, be too restricted and debilitating, and on the other hand, that it will not irritate the stomach, will require careful study of the individual case, and a thoughtful adaptation of the diet to the patient's means. This is further complicated by the fact that many of these patients are uncontrollable, and it will often be found exceedingly difficult to get them to adopt and follow out any special line of treatment.

In some cases in which the irritation of the stomach and bowels is manifestly very great, you will find remarkable results follow from placing the patient on a really rigidly restricted diet. I have had under my observation for several years, a young man who had evidently overworked himself at his trade and had become an epileptic. Many members of his family had exhibited nervous phenomena of various kinds. This young man was delicate, and after he had worked at his trade (plumbing) for some time—working long hours in a cellar without sunlight—he began to have spinal tenderness, and then vomiting occurred frequently after eating. He was at this time eighteen years of age. He grew anæmic, his work became laborious to him, and he then began to have convulsive seizures, which were quite severe and were frequently repeated. There had been no history of epilepsy in this family, although his father is neurotic, and one brother has marked nervous irritability, and also incipient phthisis. This patient also suffered from gastro-intestinal catarrh, and he was put to bed, his diet restricted to milk, and minute doses of nitrate of silver and belladonna administered. This treatment was used simply with the view of im-

proving the gastric symptoms, and not with any expectation that it would influence the convulsions; and yet these convulsive seizures, which had lasted for two years, and which I had treated with a number of remedies without decidedly improving them, gradually grew less frequent, and in a few weeks stopped entirely. The treatment which I have mentioned was then kept up for a number of months, and the result was a perfect cure. This occurred four or five years ago. The young man occasionally suffers from indigestion; he then goes to bed and limits himself to milk, and in a few days he is well again. This case illustrates what can sometimes be obtained from a restricted diet, combined with rest where there is distinctive evidence of gastro-intestinal irritation, and which, combined with an exaggerated nervous irritability, plays an important part in the causation of the convulsions. But I would not pretend to recommend any exclusive system of diet or invariable restriction of the patient. One would err greatly by insisting on too much restriction. I, however, dwell upon this because there are some cases, and you will recognize them by careful study, where this is an essential part of the treatment, and to impress upon you the fact that in all cases, this is an important part of the treatment. This is further shown by the fact that patients will nearly always become worse when you allow their digestion to become disturbed, and that after some error in diet they will have an outbreak of convulsions, and that after being placed on a restricted diet, they will soon settle down to their natural condition. I think, therefore, that we may say that there is no successful treatment of epilepsy without careful attention to the diet, and that in a limited number of cases a cure can be effected by prolonged rest and an absolutely restricted diet. This need not always be a milk diet. There are other forms of diet which are applicable to special cases.

In passing, let me refer to one of these methods, which has attracted considerable attention by the success which has followed its use in the hands of its introducer, Dr. Salisbury. I refer to the diet of raw meat, or meat almost raw, and hot water, with an exclusion of all the oleaginous and starchy ingredients of the food. This is, of course, especially adapted for that type of dyspepsia in which the salivary and pancreatic juices are deficient, and there is a large number of dyspeptics who present this characteristic. The raw meat diet, even if the meat be selected with equal care, has certain disadvantages, among which the risk of infection with tape-worm is by no means the smallest one. But by rapidly broiling the meat and raising it for a moment to a high temperature, so that the activity of any ovum contained in it would be destroyed, or by the use of such care in the selection of the meat that there would be no risk of infection, the raw meat treatment of chronic disease deserves careful attention, and will produce remarkable results in a good many cases. Dr. Salisbury recommends that the meat be prepared by the American Meat and Vegetable Chopper, by which the meat is finely minced, and after twenty or thirty minutes' chopping, there is found on the surface of the meat in the tin cylinder connected with the machine, a red pulp, reduced almost to a powder, and beneath this is a

layer of reddish-gray fibre which is almost entirely indigestible. In preparing the "Salisbury steak," this red pulp is formed into pats, put into a wire broiler and broiled for four or five minutes before a hot fire. Prepared in this way, the meat requires very little mastication; and through its use, remarkable alternative effects can certainly be produced upon the system, which is the object to be attained by the use of restricted diets. Perhaps this is sufficient to explain to you the enormous importance which I attach to this element in the treatment of epilepsy.

When I saw you last I referred to the importance of rest in the treatment of this disease. There is, in all these cases, a tendency to nervous prostration, and this peculiarity in epileptic cases is not always sufficiently recognized. We are too much in the habit of regarding epilepsy as a disease subject to fluctuations which have no reference to external causes; but a careful study of the effect of diet will convince you that epilepsy is extremely susceptible to external influences, that it can be made better or worse by momentary occurrences, and that the patient's attention or inattention to a careful regulation of his diet, to proper habits of life and modes of exercise, has much to do with the rarity or frequency, and the mildness or severity of the attacks. Attention to this point has shown me that many epileptics, as long as they avoid over-fatigue or over-excitement, will have none or only few and slight spells, but that over-exertion just as over-excitement is sure to be followed by an outbreak of one or more convulsions. The effect of excitement upon epileptic seizures has long been recognized. I have patients under observation now whose histories I have known for many years, and in some longer than my own life, in whom convulsions occur only at moments of extreme excitement. I have one, a man of the highest intellectual ability, who will go for three or four years without a spell, but if he allows himself to be overwrought, will have a series of attacks lasting perhaps for twenty-four hours. After resting for a week he is able to return to his work, and enjoys complete immunity for several years. History is full of instances of men of remarkable intellectual vigor and emotional power, who at times of excessive exertion or excitement became epileptic. From these marked examples of the effects of excitement down to what we see in the ordinary epileptic, there is every gradation of susceptibility to such causes. This is even more marked in the milder forms of the disease.

There is a class of cases to which the name petit mal has been given, which I allude to here partly on account of their diagnostic importance, and partly because they so well illustrate what I have just now been saying. These cases are extremely common. The patient never has a full convulsive seizure, but at more or less frequent intervals he will have attacks of transient unconsciousness. These attacks may be often repeated, even several in a day, or they may come at long intervals. They frequently occur at night. These spells are just as truly epileptic as are those attended with severe convulsive movements, nor is it a very favorable form, often proving extremely obstinate and rebellious to treatment; not rarely it passes into the fully developed form of

greater epilepsy, and even when it does not do so, this form of epilepsy is often followed by grave effects upon the mind and character of the patient. It is therefore a form of epilepsy of the gravest significance and of the greatest importance. Petit mal assumes different forms, sometimes so slight that it is not recognized for years. Parents will often say that their child has had holding-breath or gasping spells for a long time. These are attributed to some trifling cause, and the fact that they are the evidences of one variety of epilepsy is not recognized. They are sometimes so slight that it is not surprising that they escape detection. It may simply be an instantaneous pause and then a resumption of what is being said or done, without the patient being aware of the interruption. I have under observation a large number of these cases who are liable to these spells, and it is distinctly my opinion that the attacks are increased, and sometimes actually induced, by exertion, fatigue, or excitement; and not rarely have I found patients, more particularly women who never had these spells except when greatly fatigued. For instance after menstruation, when the system is especially sensitive, exertion will be followed for a day or two by these seizures. By recognizing this element of nervous exhaustion, and carefully guarding against such exhaustion, I have repeatedly seen this type of epilepsy slowly decline and entirely pass away.

I am now treating a lad of ten years, the son of highly neurotic parents, who suffers from these slight attacks, which he describes as feelings. He is an extremely bright lad, and stands at the head of his class at school. He is conscious of a little aura, beginning behind the sternum. The boy has been under treatment some four or five years, but neither diet nor therapeutic measures have controlled the attacks. A short time ago, I took the boy from school and ordered him to stay in bed until eleven o'clock in the morning, when he gets up and walks about or plays for a couple of hours. He returns, lies down, and takes his dinner in bed. An hour or two after dinner, he again rises and exercises for a couple of hours, and then goes to bed. His diet is carefully restricted. He is taking cod liver oil with lactophosphate of iron, but no bromides or other remedy to check the attacks. Yet under this treatment decided improvement is for the first time reported. The boy says that the spells are only half feelings now, that he does not lose himself. His mother states that she has not seen any, even transient, unconsciousness for a number of days. Previous to this he would have at least three attacks a day. If the improvement continues, I shall keep up this limited rest. If it does not, I shall make the rest absolute, keeping him in bed for a number of months. But here, both in children and in adults, comes the difficulty of restraining these patients, and this is far worse in adults than in children. After the disease has lasted a little while, there is a marked effect on the temper, and often on the intellect of the patient.

I wish to show you now a little child who presents the saddest form of this disease. He is eleven years old, and has been in the institution for four years. We have, for want of a better place, sent him to the insane asylum. The his-

tory is that he was in perfect health until three years old, when he fell down stairs, receiving a severe injury to the head. From that time to the present he has been subject to epileptic attacks, mostly of the milder form, although he sometimes has severe seizures with violent convulsions, and foaming at the mouth. His intellect soon became impaired, and this was followed by a total disappearance of the power of speech, which he had in a good degree at the time of the injury, so that he is now absolutely aphasic. When placed under treatment with bromide of potassium and sodium, he improves—that is to say, the attacks are less frequent. Some other remedies, such as hydrobromic acid, produce no effect, or make the attacks worse. It seems necessary to keep him on the use of bromides. He seems to possess little more than brute instinct. He requires constant care, and unless carefully watched, will carry the most filthy articles to his mouth. If we had seen this child seven or eight years ago, soon after the fall, it would have brought up the questions in regard to operative measures which I considered at the last lecture. Whether the injury was the sole cause of the epileptic attacks, or whether the child had an epileptic tendency which was simply called into life by the injury, we can not now say, for our knowledge of his previous history is very slight. A careful examination of the skull shows no sign of old depressed fracture, and we have nothing to guide us to the seat of the lesion; nor do I think that at this period after the injury, and in the absence of paralysis, or anything else to indicate the seat of the lesion, it is proper to interfere in any operative manner. The brain has been arrested in its development, and is certainly organically affected by the injury.

Such cases as this make us almost wish that in some painless way we had the power to take human life; for this child living, as he may do, to be an old man, will always be dependent on public charity for his care. In thousands of families there are such children scrupulously hidden from all knowledge of the public, acting as a drag upon the entire family circle, by the sadness of the symptoms and the incessant watching, and the painful incidents that are connected with the progress of such cases. From such cases as these you can readily understand of what great importance is the course of action which you decide upon when called to treat this disease in its incipient stage.

I shall now refer to the drugs which are to be used in the treatment of epilepsy. All the drugs known to man have been used in this disease, and of very few of them can it be said that they are innocent: most of them are injurious. Some of them are used simply for temporary purposes, for the improvement of the digestive functions, for the regulation of digestion, for overcoming constipation, and the like—though, as a rule, I think the less we use drugs for these purposes, and the more we depend upon regimen and diet, the better it will be. In certain cases, nutrients and tonics are necessary, and you will often find iron, cod-liver oil, preparations of the phosphates and hypophosphites called for to remedy the condition of malnutrition. Where positive indications for the use of these drugs are not present, their administration is, of course, undesirable. They

should not be given from any theoretical view, but given in the same conditions as call for their use in other diseases.

In addition, there are certain drugs given with the view of controlling the occurrence of the spasms. Until the discovery of the great anti-convulsive powers of the bromides, all forms of anti-spasmodics and anodynes had been used for this purpose, and of them, it may be truly said that nearly all of them were injurious far more than beneficial. There are cases in which these drugs are to be used to fulfil special indications. Certain remedies directed to the nervous system, as the oxide and valerianate of zinc and preparations of silver, notably the nitrate, have well established cures to their credit. There is a widespread impression among the populace that nitrate of silver cures fits. Many of those suffering from argyria are people who, suffering from epilepsy, have gotten hold of a prescription containing nitrate of silver, and have on their own responsibility continued its use for a long time. It is not an easy thing to produce argyria, and it requires a good deal of nitrate of silver to do it; but if a person takes half a grain of the drug, three times a day, for from eight to twenty-four months, intense discoloration of the skin will be produced. Nitrate of silver has undoubtedly cured a certain number of cases of epilepsy. When we reflect upon its mode of action, it is difficult to think that its good effect is due to a direct influence upon the nervous system. The cures effected by nitrate of silver seem to have been in cases in which a marked tendency to epilepsy has been associated with disturbance of the gastro-intestinal canal, which has served as a source of peripheral irritation, and this cause of the convulsions having been removed, the patient has recovered. In such a case, its effect is not due to a direct influence upon the nervous system, but to its well-known alterative action upon the surfaces with which it comes in contact. This is another illustration of the importance of attending to peripheral conditions. I presume that arsenic, in the same way, by its alterative and stimulant action, in removing anæmia or some malarial condition, or some trouble of the abdominal organs, has taken away the cause predisposing to the convulsion.

As you know, there is a class of anti-convulsive remedies which contain nitro-glycerine, nitrite of amyl, and all the bromide series, of which the bromides are the most valuable. Their discovery has greatly modified the treatment of epilepsy, and has enabled us to control symptoms in nearly all cases, and to effect a cure in a certain proportion of cases otherwise totally hopeless. Few more valuable additions have been made to the pharmacopœia than is this class of remedies. A vast deal of damage has been done by the reckless and excessive use of the bromides, but great good has been done by a proper and judicious use of these remedies. There are certain plain rules which can be laid down in regard to the use of bromides in epilepsy.

The bromides should at first be given in small doses, and only one of the bromides be given, I do not care which one. After studying the effect of this, larger doses may be given, a combination of bromides or another bromide substituted for the first one given, if the effect is not satisfactory.

The evidences of bromism must be carefully watched, for not only should you look for acne, but also for evidences of mental weakness and nervous depression, which are among the worst results of the constitutional action of these drugs. When these symptoms are produced, the bromides are doing more harm than good, even if they control the attacks. The use of large doses of bromides under these circumstances may produce secondary trouble more serious than the original disease. Nor should the use of bromides be permitted to become too habitual. Of course, some exceptions to this rule have to be made. There are persons who are perfectly well while using the bromides, but who, on stopping them, begin to have convulsions. The spells may be held absolutely in check by doses of from ten to fifteen grains of bromide of potassium or sodium three times a day, although they continue this dose for years. These are instances of the best results of these drugs. In the average case, the result is not so good. While a full dose is taken, the patient is better, but still continues to have a few attacks. Under these circumstances it is better to interrupt the use of bromide for a time, and either substitute some other anti-spasmodic, or allow the patient to go without any drug for a time, than to keep it up constantly and increase the dose as the patient becomes habituated to it.

You will find the details as to administration in your books. Acne can often be prevented by associating a little arsenic with the bromide. The great underlying principles are that the bromides should be used at first in small doses, which may be cautiously increased; that where they are continued for some time, changes should be made in the mode of administration; that a careful watch should be maintained lest symptoms of a serious bromism appear, and on their development, the bromide should be stopped, no matter how urgent is the apparent necessity for its continuance; that where the attacks are not absolutely controlled, the bromides should be occasionally interrupted in order to allow the patient to regain his normal condition, instead of increasing the dose, that only in those cases in which the bromides procure complete, or almost complete immunity, should their use be continued without intermission for a long period of time; and that while employing these remedies care should be taken to prevent disturbances of digestion from their administration.

MEDICAL SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Thursday evening, December 27, 1883. The President, Dr. Tyson, in the chair.

Case 1. Fracture of the Base of the Skull.

Exhibited by Dr. Guy Hinsdale.

J. H. W., æt. 50, fell on the ice December 8, 1882, striking upon the stone pavement. The blow was received upon the posterior and left side of the skull, and the skin was not broken. He was shortly after admitted to the Episcopal Hospital, and was totally unconscious. Blood was

found flowing from his mouth and left ear, and his nose contained clots. His pupils afforded no evidence of his condition, because of an iridectomy which had been performed on both eyes some years previous. He talked incoherently; breathing was labored, and at times stertorous. Paralysis of the left leg was noted.

Blood continued to issue from the left ear, and on the second day the discharge became thin, and continued serous until his death, which occurred on the eleventh day. The urine was examined several times, and found to contain sugar in moderate amount, but no albumen. Urine was passed freely. The patient never regained consciousness; he became more stupid, and paralysis of the left leg remained.

At the autopsy a superficial clot was found over the brain beneath the seat of injury. A very large clot was found over the right frontal region, beneath the membranes, and filling the sulci between the convolutions. This was the result of the counter-stroke, the force having been first received at a point diametrically opposite, and fully accounts for the left-sided paralysis. The fracture was slightly over five inches in length. It extended from a point in the left occipito-parietal suture, one and a half inches behind the temporal bone, and traversed the suture, passing through the petrous portion of the temporal, the auditory canal, close to the inner side of the foramen ovale, towards the foramen rotundum, where it terminated.

Case 2. Necrosis of the Temporal Bone and Brain Abscess.

This specimen was removed from the body of Margaret P., æt. 46, who died in the Episcopal Hospital, September 21, 1882, after long-standing aural disease.

In early childhood she had scarlet fever; this was followed by aural catarrh, and the discharge from her ear continued until death. She stated that when twenty-two years of age a polypus could be seen in her ear. Fifteen years ago this was removed; again masses were removed thirteen years, two years, and one year ago.

In May, 1883, four months before her death, the patient consulted Dr. Burnett, who has very kindly furnished me with notes of that date. The patient presented, at that time, a most wretched appearance. Extreme weakness, pallor, and emaciation betrayed the intense suffering of this unfortunate woman. Paralysis of the right side of the face had occurred during the previous winter, without the supervention of additional ear symptoms. At the time of examination she presented great sensitiveness of the auriculo-temporal nerve, and complained of intense pain over the right temporal bone. To control this pain, she was accustomed to use morphia suppositories. An examination of the ear revealed a mass of granulations filling the entire lumen of the auditory canal, half an inch from the entrance. Late in May a large polypoid mass was extracted; bare bone was then discovered on the posterior portion of the canal, the channel narrowed and blocked with granulations. About two fluid ounces of blood escaped after removing this mass.

When I saw the woman at the hospital in September, she was in a very low state, and evidently near her end. Her mind was seriously affected,

conversation was impossible, and she groaned with the pain, which large doses of morphia would not altogether control. There was a moderate but constant purulent discharge from the ear and from a sinus which was found above the meatus. The whole temporal region was boggy. The probe passed in freely over an inch, and loose particles of dead bone could be everywhere felt. The disease had long been beyond the reach of any remedy, and there was nothing to be done but relieve pain and await her death.

The specimen removed embraces portions of the right temporal, parietal, and occipital bones. Almost all the temporal bone has been destroyed. Only the mastoid process and the upper border of the squamous portion remain. An area of bone $1\frac{1}{2} \times 2$ inches has entirely disappeared. Adjacent to this region, and lying next to the middle fossa of the skull, was a brain abscess, the walls of which were greatly thickened. On opening this cavity, about an ounce of thick yellowish pus was found. A probe easily reached this cavity through the auditory canal and the sinus above it, and many loose fragments of bone were found at the outlet. The styloid process was found loose, but held in position by the various ligaments that arose from it. The inflammatory process, in which the meninges had of course shared, was not acute, the brain substance beyond the abscess walls had no unusual appearances, and the left cerebral lobe with its membranes were normal.

Dr. C. H. Burnett thanked the Society and Dr. Hinsdale for the opportunity of seeing this very interesting specimen, and of making a few remarks upon the case. The great destruction of bone tissue is remarkable and unusual in extent, being three inches in length, and one and one-half to two inches in breadth. The necrosis seemed to have originated in the tympanic region rather than in the mastoid, and hence belongs to the class of cases second in frequency—the most frequent being those fatal cases where the bone disease originates in and extends from the mastoid cavity. The case when seen by Dr. Burnett in the spring of 1883, presented very grave symptoms, and the patient was extremely weak; so much so that Dr. Burnett was surprised that she lived until September. The occurrence of extensive granulations in the external auditory canal constituted a very unfavorable feature, as they acted like a dam, preventing the escape of the products of inflammation, and held them back in the tympanic cavity and mastoid cells, forcing them to break an escape through more important and vital tissues. The case furnishes another example of the evil of neglect of purulent disease of the ear. Dr. Burnett inquired whether there were symptoms of destruction or implication of any of the nerves passing through the cavernous sinus, as would be shown by alteration in parts supplied by the oculo-motor, the pathetic and ophthalmic nerves.

Dr. Hinsdale replied that no eye symptoms had been ever detected.

Case of Phthisis with Empyema.

Presented by Dr. H. M. Fisher.

The patient, J. C., æt. 21, was admitted to the Episcopal Hospital, March 17, 1883. The following notes of the case were taken by Dr. George M. Boyd, the resident physician:

Patient states that he has had a slight cough for one year, but was not much annoyed with it until about one month ago, when he was seized with severe pain in the left chest, accompanied by chilly sensations and difficulty of breathing. Upon admission, he presents all the symptoms of left pleural effusion, absent vocal fremitus, tubular breathing, and bronchophony in the neighborhood of the spinal column on the left side. His chest was tapped on the morning of March 21, and three pints of a semi-purulent fluid were evacuated. The operation was followed by great improvement in the patient's symptoms. Three weeks later he left the hospital, contrary to advice. He was readmitted April 20, and stated that soon after leaving the hospital, the pain in the side returned, followed by dyspnoea.

April 23. Paracentesis thoracis was performed by Dr. Henry, and fifty-six ounces of purulent fluid were drawn off, and the operation again afforded great relief. A violent fit of coughing followed the withdrawal of the canula. The heart's apex beat was found, before the operation, to be immediately below the right nipple; after the operation, it was found to have shifted one inch to the left, or its previous position.

May 5. Dr. Forbes operated at Dr. Henry's request, making two openings into the left pleural cavity, one at the fifth interspace, the other at the fourth, and to the right of the first. Ten ounces of purulent fluid were withdrawn by means of aspirator, and a soft rubber catheter was passed in at one of the openings and out at the other. The pleural sac was then ordered to be washed out daily with a solution of corrosive sublimate gr. i.- $\frac{3}{4}$ j.

During the summer the patient's general condition seemed for a time to improve; his appetite, however, continued obstinately bad, and he had constipation alternating with diarrhoea. In October it was noted that he was losing flesh and strength rapidly, and that there was much oedema of the feet and legs. During this month diarrhoea became a constant symptom, and death occurred November 22.

Post-mortem Examination, Ten Hours after Death.—The body is extremely emaciated. The left lung is contracted to about one-fourth of its normal size, contains in its upper lobes some cheesy masses with areas of catarrhal pneumonic infiltration. The left pleural cavity contains about five ounces of ichorous pus. The parietal layer of the left pleura is so tightly adherent to the chest wall that it is impossible to detach it without dissection. The pulmonary layer is also tightly adherent to the contracted left lung, the lobes of which are firmly matted together by adhesions. The right lung also presents numerous cheesy foci, with large areas of catarrhal pneumonic infiltration. The heart is rather small, and its tissue is pale, but its valves appear normal. The liver weighs 6 pounds $6\frac{1}{2}$ ounces, its tissue is pale, and it has a *markedly waxy appearance*. The spleen is much enlarged, its tissue *firm and of a dusky-red hue*. Numerous *yellowish-white nodules* are also seen in it, the largest of which is perhaps the size of a small pin's head. The kidneys are rather large, their capsule is non-adherent, and their tissue rather paler than normal. Numerous *minute whitish nodules* are also found to be scattered through

the tissue of both kidneys. These appear rather more numerous and larger in the cortical portions, but are also found in the medullary portion. From some of the larger nodules a whitish puriform substance can be squeezed out with the blade of the knife. With the naked eye the exact nature of the above-mentioned infiltrations of the spleen and kidneys is difficult to determine. Nothing abnormal was noticed in the intestinal tract, except in the ileum, where an area of intense congestion was noticed, about one yard from the ileocaecal valve, but no ulceration was anywhere detected.

My view of the sequence of pathological events in this case is the following: *First*, catarrhal pneumonia, with the production of cheesy foci; *Secondly*, serofulous inflammation of the pleura, with attendant exudation, which, from the start, was more or less purulent, and *thirdly*, the infiltration of the *liver, spleen*, and possibly also the kidneys, with amyloid matter.

The exact nature of the yellowish-white nodules in the spleen and kidneys being yet undetermined. I cannot yet assign to them a positive place in the chain of serofulous processes; but, from the absence of any macroscopic evidence of embolic infarctions, or of any appearance of infarction in the one microscopic section of the kidney I had the opportunity of examining (kindly made for me by Dr. Henry), I should conclude that these were also cheesy foci, and their production may perhaps have nearly coincided in point of time with the production of the cheesy foci in the lungs above alluded to.

Dr. Shakespeare said that the specimen was a good instance of miliary tuberculosis. The small collection in the spleen might be tuberculous, he thought, and should have been examined for tubercle bacilli. He adverted to the successful employment of very weak solutions of corrosive sublimate in washing out suppurating serous cavities.

Atheroma, dilatation, and aneurism of the aorta atheroma of some of its branches; death from rupture of the aneurism into the left pleural cavity; congenital deformity of the stomach; malposition of the transverse colon and right kidney; irregular shape of the kidney; anomalous origin of the renal arteries and of the ureter.

By J. H. Musser, M. D.

This remarkable series of specimens illustrate how serious a disease can be in progress within the body without any manifestations. The patient had been under the care of Dr. Ludlow, in the Presbyterian hospital, complaining of and being treated for nasal catarrh. He complained also of a slight bronchitis, but not being very decided, the nasal trouble alone was treated. A white man, æt. 63, well nourished, of temperate habits, and by occupation a wheelwright; he was under observation ten weeks; no previous illness. He slept well the night before his death, until 5 a. m. He then told the night nurse he was very cold. Being covered, he went to sleep apparently; an hour afterwards he was found dead. The writer made the autopsy, about twelve hours after death.

Inspection.—Rigor mortis well marked; body well nourished; no scars or bruises; no ecchymoses; abdomen moderately distended; in the right lower

quarter a decided swelling was noticed, almost filling that area, and resonant on percussion.

Section.—Abdominal cavity first examined. The above described swelling was due to the cæcum and transverse colon. The ascending colon extended about half way the usual distance, and then turned at a sharp acute angle into the transverse colon. The latter descended parallel to the former into the right iliac fossa, and from thence diagonally upwards across the abdomen to the usual place of junction with the descending colon. The omentum contained a considerable amount of fats. The right lobe of the liver could not be seen until removal of the ribs, when it was found two inches above their margin, and to be only $2\frac{1}{2}$ inches in length in the nipple line. In the median line this same perpendicular length was three and one-half inches. More of the left lobe was visible than the right. Along the edge of the left lobe, from the median line, four and one-half inches in length, extended the *stomach*. It appeared to be small in size. When removed, it was found to be divided by a constriction five inches from the fundus; from this constriction to the pylorus the length was four and one-half inches. The first, or cardiac end, was much smaller than normal, the walls and mucous membrane healthy. The second portion was a mere tube with thick walls. The thickening was due to the hypertrophy of the longitudinal muscular layers, and to the folds that the mucous membrane was thrown into. These folds were very marked, longitudinal, and on their crests congested. The peritoneum was opaque and thickened. The *liver* was smaller than usual also. The capsule was thickened and opaque along the edges of the right lobe; on its convex surface there were cicatrices and a firm adhesion at one point to the diaphragm. On section, the tissues were firm, on pressure congested. Commencing cirrhosis noted on microscopical examination. The gall-bladder projected one inch below the liver margin in the nipple line. The left *kidney* was found in its normal position. It was much enlarged, five inches long, two thick. The *pelvis* was filled with fat, the substance pale, hard on pressure, with a contracted cortical portion. The capsule tore off easily. The right kidney was found in the pelvis at the right sacro-iliac articulation. It was small in size, irregular in shape, parallel to the sacrum. The portion dipping downwards tapered to a point, being one-half inch in width: the upper portion was two inches wide. The pelvis of the kidney was filled with fat. Towards the small end of the kidney the hilus divided, one part extending upwards one inch, along one side of the organ, the other the same length on the other side; or it might be said a portion of the kidney dipped into the pelvis, separating it for an inch. The renal artery arose from the normal origin of the middle sacral. One inch from the point of origin it divided; one branch, two and a half inches long, entered one lateral hilus, if it may be so termed, the other divided two and a half inches from the main trunk, one subdivision entering the remaining lateral hilus, the other running across the floor of the pelvis to the normal end of the kidney. The ureter arose by three branches—two from the upper end, one from one of the smaller pelves.

Thoracic Cavity.—Left pleural cavity almost

filled with blood, the lung floating on the fluid. The lateral surface was adherent to the aneurism. In its removal the collapsed sac was seen on the left side of the vertebral column. The heart and aorta were removed entirely.

Heart.—Enlarged, left side especially; weight, $11\frac{1}{2}$ ounces; measurements of left ventricle, near base, $1\frac{1}{2}$ inches thick, in the middle $\frac{1}{2}$ of an inch thick, at apex $\frac{1}{2}$ inch thick; mitral valve a little thickened, aortic healthy. Atheromatous processes were present in the aorta from its beginning to the celiac axis, and extended into the latter vessel, and also the innominate and carotid arteries. These processes included the sclerotic changes shown by innumerable small, smooth, firm elevations of the surfaces, the degenerative changes, fatty and calcareous, and also the atheromatous. One calcareous plate was found in the celiac axis. From its origin to the middle of the transverse aorta, the vessel was dilated, and the characteristic fatty changes of the proliferated cells of the intima lemon-yellow colored, smooth, soft elevations, were marked. Opposite the trachea the caliber of the aorta diminished to almost normal size, and here the sclerotic changes were most marked, as well as around the mouths of the vessels. At the junction of the transverse and descending aorta, the lumen was again closed; here the aneurism originated. It was $5\frac{1}{2}$ inches long, and when distended 12 inches in circumference. It was of the true variety, but from it sprung four false aneurisms, varying in size from a filbert to a small egg. Organized clots covered the surface of portions of the wall, and on dissection it was found these clots were either in the false aneurisms or clinging to atheromatous ulcers. Rupture of the sac took place behind the pleural adhesions, and leaked into the cavity, finding its way through the adhesions. The vertebrae were not eroded, and although the sac was in contact with the left bronchus, there was no evidence of decided pressure upon it, while the relations to nerves, other vessels, and the œsophagus, were such that the usual pressure symptoms could not arise.

It is thus seen that by physical examination alone could this aneurism have been detected. There were absolutely no subjective symptoms, and the autopsy reveals the reasons of this.

Hour-glass Contraction of Stomach: Congenital.

Presented by J. H. Musser, M. D.

The patient, an adult, from whom I removed this stomach, died of organic heart disease. Constant vomiting occurred a few months before death, but as a sequence of the general condition of the patient, and not on account of the gastric changes. I call the appearance congenital, because of the absence in the clinical history of any occurrence throughout life to have caused it, and of the want of evidence on post-mortem inspection. The contraction took place in the centre and was transverse; the peritoneum and sub-mucous connective tissue was thickened at this point. Anterior to the constriction, the muscular coat was hypertrophied. The mucous membrane was thrown into folds in the constriction.

Lung from a Case of Pleuro-pneumonia, Complicated with Delirium Tremens.

Presented by J. H. Musser, M. D.

I present this specimen to-night on account of its perfection. It is the lower lobe of the right lung in the stage of red hepatization, as indicated by the appearance, weight, etc. Almost the entire pleural surface including the diaphragmatic, is covered with recent lymph, the layer averaging one-half inch in thickness. The tongue of the lung dipping into the space between the diaphragm and the thoracic wall is not solidified entirely. Here the lymph is abundant, and the contiguous portion of the lung is hepatized as if the inflammatory process extended from the pleura; this peripheral hepatized portion is but one-fourth inch wide; the inner and succeeding portion is not solidified.

The patient died eighteen hours after admission to the hospital, from heart-clot. When admitted there were evidences of its formation, and in addition he had delirium tremens. The pneumonia was distinctly recognized. There were no signs of simple or diaphragmatic pleurisy. It was remarked at the autopsy on removing the sternum, the extreme distention of the right heart, especially the auricle. On opening the heart, hypertrophied from other causes, the right side was found filled with blood and an enormous ante-mortem clot entwined around the leaflets of the tricuspid valve, and extending through the auricle into the pulmonary vessels. A similar clot was found in the left heart. The kidneys were congested, and commencing cirrhosis appeared manifest.

The history of this case antecedent to the admission to the hospital is as follows: The patient had been on a "spree" for two weeks, and five days before admission had had a severe chill, followed by the symptoms of pneumonia. Two days after the chill the mania developed, and on the day of admission he had been found wandering about the streets by a "crony," who brought him to the hospital. He was forty-one years old, a boss machinist, single, of intemperate habits.

Carcinoma of the Uterus, Fatty Kidneys, and Empyema.

By W. A. Edwards, M. D.

The specimens which I show you to-night were taken from the body of A. E. this morning. I have not, as yet, had the opportunity of examining them microscopically. The patient was visited but once before her death, by Dr. J. S. Watt, for whom I made the post-mortem examination. The history of the patient is of course imperfect, in fact little if any could be obtained; the symptom of which she complained the most was an ill-smelling, irritating discharge from the vulva; so our attention was first directed to the womb, which presents a scirrhus carcinoma of the external and internal os and of the cervical canal. The mucous membrane of the organ is softened and very rugous, looking not unlike a mammilated stomach; a microscopic section will probably show cellular infiltration. The uterus is enlarged; our subject was a multipara, æt. 45, nine children and two miscarriages. A cyst was seen in the right parovarium; its contents were pure serum. The ovaries presented areas of calcareous degeneration; other pelvic viscera normal. The kidneys are small, and appear to have undergone some amyloid change; the right one was a rib higher than its normal position. Heart muscle has undergone some fatty degeneration, as has also the aorta; valves almost normal, ante-mortem clots in each ventricle; that in the right is of unusual size. Pericardium contained the usual straw-colored effusion.

Lungs.—Left normal. Right, the pulmonary and costal pleuræ were in many places adherent by thick, well organized lymph, which beautifully illustrates the rationale of friction râles, their sudden appearance, short duration, and equally sudden disappearance. About a pint of purulent effusion was collected in the base of right chest. The diaphragmatic pleura was tightly adherent to the pulmonary, requiring some tearing in order to separate. The lobes of this lung are bound down by recent lymph. Scattered throughout the mesentery were to be seen areas of calcareous degeneration, about the size of almonds.

EDITORIAL DEPARTMENT.

PERISCOPE.

Dyspepsia as a Symptom of Kidney Disease.

The following is from a clinic of Dr. J. M. Da Costa in the *College and Clinical Record*, January, 1884: Robert E., a waiter, born in Scotland, was admitted into the ward October 15, 1883. He states that he has suffered with dyspepsia for the last fifteen years, but has had no serious illness in that time. In order to relieve his indigestion and want of appetite, he has been in the habit of taking a drink of whisky before breakfast, for ten or twelve years, and possibly more during the day, but he claims that he was not intemperate. He came here complaining of pain in his stomach, with frequent vomiting, both of food and of mucus; pain between his shoulders, constipated bowels, and bleeding piles.

Here is a man with a history of chronic indigestion, accompanied by loss of flesh; he has that peculiar melancholy look which comes from long-standing dyspepsia. He says that food lies heavily upon his stomach; he is troubled with wind, due to slow digestion; he has acid eructations occasionally, and gastric pain after meals. He states that he has lost from thirty-five to forty pounds of flesh in the last nine months. He is therefore losing flesh very rapidly, as you may see.

Before examining him, I would also tell you that he is also annoyed by palpitation or over-action of his heart. The temporal vessels are well developed; they are rather tortuous, and visibly pulsate. He has a pale, flabby tongue, showing the marks of the teeth.

Now, gentlemen, this patient, at first sight, seems like an ordinary case of chronic dyspepsia;

but the decided loss of flesh and the appearance of anæmia which he presented, seemed to me so out of proportion to the dyspeptic symptoms that I investigated the case further. This wasting and anæmia suggested a careful examination of the urine, and I think that I have found in that examination the true explanation of the case. The urine was albuminous, and it contained tubercasts; the specific gravity was rather low, 1.014. He states that he has had to rise at night to pass water, for many years. Now, you have before you a case which is of interest in this connection: This history of anæmia in a case of so-called dyspepsia is really quite the reverse; the dyspepsia is a secondary affair, and the symptoms are really due to the kidney disease. He has the form of renal disorder known as the contracted kidney, and with this the symptoms of gastric catarrh often assume such prominence as to lead to the belief that they are the only indications of disease. I point out the case as one in which the kidney disease is the most important feature. I also think that it was primary; it is difficult to say if it was really so or not, but it is not difficult to say that at the present time it is the constant drain from the kidney which causes the anæmia and impairs the general health.

I need not review the clinical features of the case of which I have just given you the key. Let us turn to the question of treatment. He was, for a time, upon a purely milk diet, with lime-water, and that was very effective in stopping the vomiting; he was subsequently allowed to eat eggs, and an albuminized diet, without meats. He was ordered five grains of pepsin after each meal, stopping all other prescriptions, and keeping him in bed. Partly with a view of improving his blood, and partly to act upon the kidney, I will now order him Basham's mixture. (3 ss. t. d.)

The Relation of Physiological Study to Pathology and Therapeutics.

In an interesting lecture in *Science*, Dr. H. Newell Martin says on this subject: I must find time to say a few words as to the connection of physiology with pathology and therapeutics. The business of the physiologist being to gain a thorough knowledge of the properties and functions of every tissue and organ of the body, he has always had for his own purposes to place these tissues under abnormal conditions. To know what a muscle or a gland is, he has to study it not merely in its normal condition, but when heated or cooled, supplied with oxygen or deprived of it, inflamed or starved, and see how it behaves under the influence of curare, atropine, and other drugs. From the very start of physiological laboratories, a good deal of the work done in them has necessarily been really experimental pathology and experimental therapeutics. I suppose to-day that at least half of the work published from physiological laboratories might be classed under one or other of these heads. And what has been the fruit? I can here refer only to one or two examples. It is not too much to say, that, though inflammation is the commonest and earliest recognized of pathological states, we really knew nothing about it until the experimental researches of Lister, Virchow, and Cohnheim; and that all we really know as to the nature of fever is built on

the similar researches of Bernard, Haidenhain, Wood, and others. As to therapeutics, so far as giving doses of medicine is concerned, it, still in its very infancy, had its birth as exact science in physiological laboratories. Every modern textbook on the subject gives an account of the physiological action of each drug. What the future may have in store for us by pursuit of these inquiries it is hard to limit. The work of Bernard—showing that in curare we had a drug that would pick out of the whole body, and act upon, one special set of tissues, the endings of the nerve-fibres in muscle—and the results of subsequent exact experiments as to the precise action of many drugs upon individual organs or tissues, hold out before us a hope that perhaps at no very distant day the physician will know exactly, and in detail, what every drug he puts into his patient is going to do in him.

Pathology and therapeutics, while almost essential branches of physiological inquiry, have nevertheless their own special aim; and, now that the physiologists have proved that it is possible to study these subjects experimentally, special laboratories for their pursuit are being erected in Germany, France, and England. These laboratories are stocked with physiological instruments, and carry on their work by physiological methods. Those who guide them, and those who work in them, must be trained physiologists; if not, the whole business often degenerates into a mere slicing of tumors and putting up of pickled deformities: pathological anatomy is a very good and important thing in itself, but it is not *pathology*. Looking at the vast field of pathological and therapeutic research open to us, and bearing in mind the certainty of the rich harvest for mankind which will reward those who work on it, I regard as one of my chief duties here to prepare in sound physiological doctrine, and a knowledge of the methods of experiment, students who will afterwards enter laboratories of experimental pathology and pharmacology immediately connected with our medical school.

Reflex Uterine Vomiting.

Dr. Grailey Hewitt thus concludes a paper on this subject in the *Lancet*, January 5, 1884:

According to my experience, reflex uterine vomiting when of an obstinate character is very frequently associated with great weakness and want of tonicity of the uterus, and a flexed condition of the organ is almost invariably also present. There are undoubtedly cases of reflex uterine vomiting in which the cause is a different one, but they are exceptional, and occur rarely. The unduly soft uterus readily bends, and any temporary increase in the degree of the flexion is attended with aggravation of the reflex disturbance—viz., the vomiting. This is a fact with which observation of many cases has made me acquainted. The several factors concerned in the production of this grave disorder may be enumerated as follows:

1. A general enfeeblement of the body, the result of a low condition of the nutritive process, in which the uterus participates.
2. The physical weakness and pliability with which the uterus is consequently affected.
3. The flexed condition of the uterus, liable to

be intensified by certain movements or positions of the patient.

The sickness and vomiting appear to result from the irritation of the uterine nerves consequent on the temporary or permanent compression of the uterine tissues. It is almost certainly relieved, or for the time, at all events, removed, by measures having for their object the maintenance of the uterus in a normal position and shape. In two of the three cases above related, immediate relief was obtained from the treatment. The third is a case in which the condition of the ovary introduces a complication and increases the difficulty.

On the diagnosis of reflex uterine vomiting I may, in conclusion, add a few remarks. There is no doubt that many cases of this affection escape true recognition, the sickness being erroneously attributed to the liver or the stomach being the seat of disease. Many cases of so-called "bilious vomiting," and not a few supposed of gastric ulcer, turn out on investigation to be cases of uterine vomiting pure and simple. As regards the liver and the stomach, it will be found possible to exclude these organs as causes of the vomiting from the fact that apart from the vomiting there is no other symptom indicative of disease of the organs in question; while, on the other hand, there are generally marked symptoms indicating that the uterine functions are disturbed. One symptom specially indicative of the uterus as the cause of the sickness is the exaggeration of the sickness which is liable to occur when the patient moves or walks or exercises herself. It must be added also that in cases of reflex uterine vomiting, where the malady has been of long continuance, the stomach itself is liable to become affected. The secreting power of the stomach is enfeebled by the long-continued starvation; and it is no longer capable of producing gastric juice to any amount, which adds another factor to the pathology of such cases. Hence, a quasi-paralysis of the gastric mucous membrane; and I have seen cases of this kind in which the extremest care was necessary to prevent a fatal issue, even after the tendency to vomit had been obviated or diminished by appropriate treatment.

Bromide of Ethyl in Obstetrics.

The *American Jour. of Obstetrics*, January, 1884, tells us that Müller reported to the German Gynecological Society, that following in the wake of the experiments repeatedly made of late (especially by Heckermann, of Berlin, fifty cases), he has employed ethyl bromide in twenty-two cases of labor. The results were not as favorable as those obtained by H. The action is uncertain. M. employed it thirteen times in the second stage. In five of these cases the labor pains ceased altogether; in three, they ceased in part; in five, no effect was produced. The drug was used eight times during the whole course of labor: in two, the effect was very good; in four, the effect was temporary; in two, the pains were obtunded only in the first stage. On the average, fifty to sixty grams of the drug were employed. During the narcosis, the pupils dilated and the face became congested. Little effect was produced on the pulse and respiration. M. believes that the re-

tardation in the activity of the contractions is merely apparent. He has witnessed no post-partum hemorrhages and no mal-involution of the uterus.

Quite noteworthy is the fact that a very severe bronchitis set in during the puerperium in two of the cases. The purity of the drug was established by chemical examination. Perhaps the quantity employed (eighty grams) was too large.

Schatz (Rostock) said he was glad that the narcosis of the normal parturient had not thus far become the rule in Germany. The kymographion shows that chloroform narcosis considerably reduces the force of the contractions. He ascribes the large number of post-partum hemorrhages in England to the frequent employment of chloroform. He fears that similar drawbacks attend the use of bromide of ethyl.

Neugebauer (Warschau) called attention to some points in Heckermann's lecture, which he had heard in Berlin; he stated that Rose likewise had experimented with the drug. The latter objected to it because the odor of the expired air of persons anesthetized with bromide of ethyl was disagreeable to patients in the same ward.

Mueller stated that he, too, had noticed a garlicky odor in his patients, but it was never strong enough to be really objectionable. He added that the drug seemed to affect the fetus rapidly, the expired air of which likewise diffuses that odor.

Hegar had tried various anesthetics, but had always returned to chloroform. Ether may also be the cause of violent bronchitis which may be fatal to debilitated persons. Bichloride of methylene has the advantage that it has no depressant effect on the heart. Breisky has had one case of death from this drug. Chemical examination showed that the preparation was a mixture of chloroform and alcohol. H. likewise had his sample tested. The result was the same. He thinks it advisable to put the patient under chloroform toward the end of the second, but particularly of the first stage.

Mueller had also experimented with chloral (five grams). The pains were moderated in the first, but not in the second stage.

Trephining in Head Surgery.

Dr. S. H. Benton contributes an article on this subject in the *Proceedings of the Medical Society of the County of Kings*, which thus concludes:

The deductions I draw from my own experience in head injuries, are:

1. That almost all compound depressed fractures of the skull, without operative interference, are fatal.
2. That there is great danger in making a simple fracture of the skull compound, is more imaginary than real.
3. That the therapeutic method is negative, and a virtual surrender to death.
4. That the trephine, early used, is the best, and I think we can safely say the only agent in the hands of the surgeon to save life in these cases.

The after treatment forms no inconsiderable part in conducting our cases to a successful issue. I refer more especially to the local treatment.

There are no capital operations where antisept-

sis can be practiced with greater profit, not excepting abdominal surgery, and it should be carried out to the most minor detail. The agent I have used, in all my cases, has been carbolic acid.

I am careful to remove all spicula and bone dust from the wound. I remove all depressed fragments, unless I am satisfied that their attachment to the skull is broad enough so as that the nourishment shall not be interfered with. I take no chances in this respect.

The wound should not be drawn together by sutures, with the hope of securing union by first intention. You may, if you choose, draw the edges of the wound reasonably near together, but not quite.

There must be a chance for free drainage of the debris, if any be overlooked, as well as the natural products of inflammation, which, if confined, would undoubtedly produce the usual result, viz., septicæmia, and all that that implies. Some one has told us that "cleanliness is next to godliness," which, in these cases, as well as most cases of surgery, is true; therefore I keep the wound scrupulously clean, giving it my personal attention, and trusting to no nurse for this.

If any part of the brain should protrude later in the case, as usually occurs if the dura mater is much injured, I slice it off with the knife. This I find to be the best plan, as I have found it impossible to bring pressure enough to bear so as to press it back, and two or three times alarming head symptoms were produced by the effort. Astringents I have found useless. I have never seen ill effects follow the use of the knife.

The indications for internal medication in all my cases have been very few. They were all young and vigorous subjects, as well as temperate in habits.

No medicine was given, unless there was a present indication for its use—nothing for a possible future complication.

★ *Treves refers.* A New Disease.—*Actino-mycosis*. We find the following in the *Brit. Med. Jour.*, January 12, 1884:

Some little time ago a man living in a secluded country district, consulted Mr. Treves, of Margate, on account of a number of sores, which had made their appearance on the side of the neck and on the chest. The first sore had "come of itself," about two years ago, on the left side of the neck, just above the clavicle; subsequently the others appeared, one after the other, to the number of four, in an oblique line across the chest. The largest of these, the one nearest the primary sore, was the first to appear, and the others appeared as they were arranged, in series; there was also over the left side of the jaw, near the primary sore, another, pierced by a sinus leading down to the bone. The circumstances evidently suggested some infective process; the first sore was an excavated ulcer, with an irregular caseous-looking base, but the sores below this projected from the surface as much as half an inch in their centre, had a semi-gelatinous look, and an excoriated surface. Altogether, these latter sores rather resembled the small growths seen in some cases of sarcoma of the skin; but the case, taken as a whole, was evidently not one of sarcoma, and after due

consideration, Mr. Frederick Treves, of the London Hospital, to whose care the patient had been transferred, exhibited the patient at the Pathological Society, as probably a case of actino-mycosis. The disease has been known to veterinary surgeons as maxillary sarcoma, and the whitish tumor substance produced was the simple embryonic structure seen not only in some sarcomata, but also in the infective new growths. Bollinger had shown that the tumors contained in cavities in their interior little yellow bodies, which consisted of matted masses of mycelium. This fungus, from the peculiar radiate appearance presented by it in sections of the growth, he named actino-mycetes. Israel, of Berlin, first described the disease in man, and attributed it to a new form of fungus, but without apparently identifying it with the disease of cattle, as Ponfick did later. However this may be, there will, we imagine, be little question that this case now brought before the profession by Mr. Treves is the first which has been recognized in this country, that is, if the diagnosis which is at present made tentatively prove to be correct. On this point the only positively conclusive evidence is the discovery of the fungus; and on Saturday last, at the London Hospital, Mr. Treves examined the growths, which were distinctly pedunculated; and Mr. Watson Cheyne, who holds one of the Research Scholarships of the British Medical Association, will, we understand, make a complete examination.

Hygiene vs. Diphtheria.

In the *Cinn. Lan. and Clinic*, January 26, 1884, Dr. Mary J. Finley discusses the recent epidemic of diphtheria at Mansfield, Ohio, and thus concludes:

After a full consideration of all the facts which I have been able to gather, I can only arrive at the conclusion that neither sanitary conditions nor water supply, either originated the present outbreak of diphtheria in this city, contributed to its spread, or increased its virulence—except in so far as the cold, moist atmosphere from damp cellars conduces to catarrhal affections of the respiratory mucous membrane, rendering it weaker to resist the special contagion of diphtheria, and in so far as the general deterioration of vital processes induced by any impurity of air or water, renders the system less able to throw off the poison of disease, and less able to maintain its integrity until the disease shall have spent its force.

While the present report shows that there may be some connection between the malignancy of diphtheria and bad sanitation and impure water, yet the very multiplicity of the presumed unsanitary conditions precludes the possibility of ascribing a specific influence to any one of them. Well water, sewer gas, damp cellars, foul soil, rotting garbage, and filled lots, appear to have exerted an equal influence. Are we to suppose that the special poison of diphtheria is engendered by or finds its favorite nidus in each of these? Yet to each of them has been ascribed with as much justice the causation of various other diseases, typhoid, scarlet, and yellow fevers, dysentery, cholera, erysipelas. Must we believe that each of them possesses some half dozen different

poisons, each of which is at some time, for some unexplained reason, in the ascendant? Or shall we not rather believe that given the specific cause producing any epidemic disease, all factors which tend to a lowering of the standard of health render the individual more liable to succumb to its influence and less able to endure its effects?

A careful study of a number of reports on diphtheria in different parts of the United States and in other countries, has convinced me that epidemic diphtheria occurs with almost equal malignancy under the best and the worst sanitary conditions. The most desirable hygienic surroundings, and the most irreproachable water supply, afford no security against its attack.

The Treatment of Gangrene of the Lung.

After reciting a case, in the *Dublin Jour. Med. Sci.*, January 1884, Dr. Finny formulates the following propositions:

1. That the primary indication in cases of extensive gangrenous cavities is to prevent the putrid matter becoming a centre of infection, and thereby not only poisoning the whole system, but by its direct contact (a) causing an extension of the gangrene in the neighboring tissue of the lung, or (b) by being sucked into the bronchi of the other lung or other lobes of the same lung, inducing a gangrenous broncho-pneumonia. In the words of Hertz (*Ziemssen's Cyclop.*, Vol. V., p. 431) "the *indicatio morbi* also imperatively demands the evacuation of the sputa out of the cavity," and in connection with this I may mention that inversion of the patient's body, as in drowning, has been suggested.

2. That in cases of diffuse gangrene the probability of recovery is extremely small. Indeed, according to most observers diffuse gangrene from its nature runs an inevitably fatal course, and that therefore to attempt to cure such cases by antiseptics taken internally, such as tinct. eucalypti in 6-8 grm. doses a day (as advocated by M. Renaud in the *London Medical Record*, Vol. viii., 1880, p. 229), or by inhalations of carbolic acid, turpentine, etc., is but to dally with the disease and to give it greater head.

3. That under these circumstances it is a justifiable proceeding, if not the right treatment, to provide means of evacuating the cavity of its rotten and putrefying contents through the skin.

4. That the operation of incision and tapping of basic cavities in the lung is one which has been successfully performed with immediate benefit, and that when death has occurred in cases so operated on, death has not been directly due to the operation, but rather to its not having been thorough and efficient enough.

5. That in cases of diffuse gangrene of the middle or upper lobes, operative proceedings are quite as urgently, if not more urgently, called for as when it is of the lower lobe, since from the natural gravitation from the upper to the lower lobe there is greater risk of secondary infection of the dependent part.

6. That exploratory puncture and aspiration should be first attempted, and should the cavity be reached, immediate steps be taken for incision and tapping.

7. That the incision should be over the centre

of the cavity, as well as can be accurately determined, and wherever it approaches nearest to the chest wall, and it may thus occupy the anterior as well as the posterior wall of the chest.

8. That the question as to the mode of operation is one at present upon which opinions differ, though it seems to me advisable that an incision should be made only down to the intercostal muscles, and that afterwards a trocar and canula should be passed into the lung to a depth of 3-4 inches, and that a drainage-tube of sufficient size should be substituted for the canula.

The Use of Tobacco by Boys.

In the course of an article on this subject, Dr. Edward O. Otis (*Boston M. and S. Jour.*, January 31, 1884,) says:

The evil effects, then, of tobacco upon boys which can be said to have been fairly proved by observation, are:

1. An interference with and impairment of the general development, physically and mentally. Probably it does this by retarding progressive cell change, and impairing nutrition. In an adult, the development is attained, consequently he can smoke with impunity so far as this effect is concerned, when the boy only does it with injury.

2. The tobacco heart. This likewise happens to the adult, but is, I should think, more likely to happen to the youth, and with graver result, because his is such an unstable age physically. For this same reason, the other injurious effects are more liable to be intensified in the youth.

3. Defective muscular coördination. I have but little proof to show that this condition is more than temporary, continuing only while the tobacco is used.

4. It reduces the intellectual power of the boy. It does this either by opposing mental application and effort, or else by producing deterioration of the intellect, probably both to a greater or less extent.

5. It impairs the memory. What proof I have adduced seems to show that this is a permanent injury.

6. It may cause defective vision, and also irritation, more or less chronic, to the external parts of the eye.

7. It may unduly excite the sexual system, and lead on to excesses. I have no positive proof of this, but my observation among boys rather points to it.

8. Irritation of the mucous membranes of the mouth and throat, more especially in case of cigarette smoking.

9. It may impair digestion, and produce other derangements, such as habitual uneasiness, hypochondriasis, and so on.

The Radical Treatment of Nasal Catarrh.

The following report of his experience is given by Dr. P. M. Rixey, U. S. N., in the *Proceedings of the Naval Medical Society*, vol. i.:

"The radical treatment consists in the use of either chemical or surgical measures for the partial or entire removal of hypertrophy. The first consists in the use of various caustics, such as acetic acid, chromic acid, London paste, nitric

acid, and nitrate of silver, mentioned in the order in which I prefer to use them. My choice is acetic acid for hypertrophy situated in the nostril, or when these applications have to be made through the nostril; chromic acid to the posterior nares and vault of the pharynx. Nitric acid has to be used very carefully, owing to the difficulty in controlling its action. Nitrate of silver I consider, in the final result, more stimulative than destructive. Each application of the above escharotics only removes a superficial slough, and, consequently, numerous applications have to be made at intervals from five to ten days, and in the meantime sprays or douches have to be used daily to keep the parts clean. I soon came to the decision to use them only in those cases of moderate hypertrophy, and find something more radical in its immediate effect; this is found in the surgical treatment, which consists in the use of forceps, curette, snares, actual or electric cautery, and electrolysis. The forceps and curette I have used only a few times, and usually followed with caustic. The snare I prefer is the improved Jarvis, and it works admirably when the enlargement is considerable, whether anterior or posterior. The actual cautery I have not used, but find that in galvano-cautery I have an invaluable agent, and with the Flemming improved Seiler cautery, and the electrodes displayed here, we can reach almost any portion of the space. These knives can be heated to a bright red instantly by, as you see, a simple pressure of the thumb."

Lumbar Abscess with Peculiar Symptoms.

In the *Brit. Med. Jour.*, January 5, 1884, Mr. Stear relates the case of a medical man who died in June, 1883, aged 51. He had always been a strong man, and worked hard at his profession, without ever taking a holiday. During the last four months of 1882 it was noticed that he was thinner and looked aged, but he could ride twenty miles without fatigue. At the end of January he caught cold, and was confined to his bed with severe rheumatic pains in the right gluteal region. After a brisk purge he was better and able to get up, but he did not make much improvement. On February 5th he was seen with Dr. Latham, the symptoms being vomiting after dinner and pain in the hip and thigh. He left home for Ventnor, and afterwards went to Clifton, and returned home much emaciated and very weak. He was seen again by Dr. Latham, but no tumor or evidence of spinal disease could be discovered. On April 8th, Dr. Humphry opened an abscess which had been detected in the back, a large quantity of laudable pus escaping. The discharge continued until his death, on June 25th, from exhaustion. At the *post mortem* examination there was found to be extensive disease on the right side of the bodies of the second, third, and fourth lumbar vertebrae, and erosion of the transverse processes of all of them, extending half-way along the crest of the ileum. The iliacus muscle had disappeared, and its sheath was filled with pus. There was also pus in the psoas muscle. The cartilages were healthy. The stomach was dilated. All the other organs were healthy. Mr. Stear thought it probable that the spinal disease was caused by a fall from a horse, or at lawn-

tennis in 1882. The case was of interest from the deceptive nature of the cause of vomiting and emaciation, and from the fact that, although there must have been extensive disease of the vertebrae, he was able to carry on his work.

Rubbing in the Treatment of Diseases of the Eye.

The London Med. Record, November 15, 1883, says:

This subject had been brought before the Congress of Naples by Gradenigo; he again read a paper on it in the meeting of the Ophthalmological Association in Padua (*Atti della Assoc. Ottal. Ital.*; *Annali Univ. di Med.*, June, 1883). He considers rubbing, when used intelligently, a very valuable help in treatment. He had at first limited its employment to affections of the lids, but afterwards used it in affections of the eyeball, especially with the scope of diminishing tension. He related the case of a lady in whom, by this mechanical means, he cured a severe attack of exophthalmitis, accompanied by intense pain. He believes, as the result of his observations, that rubbing is useful in diseases of the lids, of the muscles, of the bulb with increased internal tension, and, lastly, in affections of the optic nerve itself in the orbital cavity, and perhaps even when there is effusion into its sheath. By rubbing, the venous circulation of the orbit and globe is favored, and in this way the beneficial action is exerted.

REVIEWS AND BOOK NOTICES

NOTES ON CURRENT MEDICAL LITERATURE.

—Two interesting reprints, that will prove very interesting reading and suggest much food for thought and reflection, have been received from the *Alienist and Neurologist* for January, 1884. The papers are by Dr. C. H. Hughes, of St. Louis, and are entitled, "The Opium Psycho-Neurosis—Chronic Meconism or Papaverism," and "Borderland Psychiatric Records—Prodromal Symptoms of Psychical Impairment."

—Messrs. Palliser, Palliser & Co., architects and publishers, Bridgeport, Conn., have issued a series of charts entitled "Palliser's Useful Details" (price \$3.00), giving a variety of useful designs for the construction and ornamentation of buildings. Their plans impress us as sensible, fresh, and decorative, and any of our readers who contemplate building will not regret acquainting themselves with the architectural suggestions and resources of this firm.

—In a reprint on the question, "Shall we Put Spectacles on Children," Dr. Julian J. Chisholm, of Baltimore, answers quite decidedly in the affirmative in all cases where a defective eye renders the sight imperfect. He combats the pre-

vailing notion, which he says is often supported by the family physician, that the use of spectacles at an early age tends to increase and strengthen the optical defect.

—In a reprint from the American Surgical Association, Dr. N. Senn, of Milwaukee, Wis., enters very fully into the treatment and general conditions of fractures of the neck of the femur, with special reference to obtaining bony union after intra-capsular fracture. He offers a new mechanical contrivance of his own, the results from which have been very satisfactory. The paper is well worth careful perusal.

—The report of the proceedings of the sixteenth annual meeting of the Society of the Army of the Tennessee makes a pamphlet of nearly 200 pages. It may be obtained of Gen. A. Hickenlooper, Cleveland, Ohio, and will doubtless interest those of our readers who served in that branch of the national forces.

—The *International Review of Medical and Surgical Technics* is a promising addition to medical literature. It is published quarterly, and is the official organ of the American Association of the Red Cross. Its editors are Drs. J. H. Warren, C. E. Warren, and W. E. Smith. It is published at Boston, 51 Union Park, and the price is \$3.00 a year. Its special field is everything new in the mechanical devices applicable to medicine and surgery.

—The operation of the extirpation of the uterus for cancer is severely condemned as unjustifiable by Dr. A. Reeves Jackson, of Chicago, in a paper before us. He sums up his impeachment of it in the following words:

1. Diagnosis of uterine cancer can not be made sufficiently early to insure its complete removal by extirpation of the uterus.
2. When the diagnosis can be established, there is no reasonable hope for a radical cure; and other methods of treatment far less dangerous than excision of the entire organ are equally effectual in ameliorating suffering, retarding the progress of the disease, and prolonging life.
3. Extirpation of the cancerous uterus is a highly dangerous operation, and neither lessens suffering—except in those whom it kills—nor gives reasonable promise of permanent cure in those who recover. Hence it fails in all the essentials of a beneficial operative procedure, and should not be adopted in modern surgery.

His examination of the statistics of the operation bears out fully these positions.

—The thirty-first annual report of the Children's Aid Society of New York City (No. 19 East Fourth street) gives a thoughtful person much food for reflection, and to the philanthropist a

glimpse of how wide is the field for charitable effort. In turning the leaves we have been impressed with the analysis of the causes of profligacy among girls, as stated by the experienced matron of one of the Girls' Lodging Houses. The passage is as follows:

What are the causes of so much ruin and destruction? The earliest is, we believe, foolish and immoral reading indulged in by girls, even before they are old enough to earn a living, and just when character is forming. This is the worm in the bud, which parents should watch more closely. Inordinate love of dress and inability to get it honestly sweeps off many. Idleness, ungoverned natures, and false pride, are fruitful sources of degeneracy. There is also a slackening of the sense of responsibility as to the kind of life followed, most serious in its results, as it takes away the motive for effort in the direction of industry and virtue. In the case of poorly-paid seryant girls other causes come in, but the great lack everywhere seems to be the right kind of personal influence.

We do not remember to have seen elsewhere such a positive charge against foolish reading (novels and story papers), but we have little doubt that it is correct.

BOOK NOTICES.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE DEPARTED FEE BILL.

Not long since, a correspondent in a distant state sent to us to obtain for him copies of the fee-bills of this and neighboring cities. We had to reply to him in a paraphrase of the needy knife-grinder of Anti-Jacobin renown—"Fee-bill, God bless you, we have none to show, sir!"

The time was when a printed document of that kind was gravely determined upon at a society meeting, and carefully laid away in the office drawer, to be produced for its effect on grumblers who made a fuss about the physician's charges. That was its principal if not only use, for as a rule to the physician himself in making his charges, it was far more honored in the breach than in the observance. At last it disappeared even as an empty formality, and every doctor was left free to charge little or much, which was generally pretty closely governed by what he thought he could get.

There seems no other way of regulating charges. So much depends on the personal skill of the individual, the demands upon his time, the nature of his specialty, the class in life of his patient, the intricacy or simplicity of a given operation, and other such variable factors, that it becomes practically impossible to lay down any one rule, and still more impossible to have a rule respected.

Unpleasant consequences result from this occasionally. Persons, especially heirs, may object to charges as excessive; and as no established tariff can be shown, the only ultimate appeal is to a jury. One physician obtains a reputation for excessive charges, which another may take advantage of. The young practitioner is often at a loss what to estimate his services at; while the one who is in the hey-day of his fame may be, and often is, extortionate. Having nothing to instruct him as to what a physician should ask, the patient or his friends may be forced to make a bargain beforehand, and the physician has to chaffer in a manner not agreeable to him nor advantageous to his dignity.

The general custom of the profession in a given community may be arrived at, but it is no sort of

guide for particular instances. More frequently, however, the doctor receives less rather than more than a fair average return for his labor.

While we regret the decadence of the fee-bill, we recognize it as a necessary loss in populous and active centres. It may survive in rural and stationary populations, but it cannot be resuscitated in the great cities. There the "personal equation" comes into the sum too much to allow it to be represented by any fixed figures. The fee-bill is a reminiscence, which belongs no longer to the present day.

AN APPEAL TO THE PROFESSION.

Last month a circular letter was sent to a number of physicians in this city, and a second of similar tenor to the county medical societies of this State, asking contributions to a fund to recompense Dr. William S. Forbes for the expenses incurred in defending himself in a suit brought against him last winter. The circular explains the whole matter, as follows :

It is generally known to the profession throughout the State of Pennsylvania that Dr. William S. Forbes, while in the discharge of his official duties as Demonstrator of Anatomy in the Jefferson Medical College, was subjected to a very unjust and expensive suit at law, under the charge of having violated a private cemetery for the purpose of procuring dissecting material. The result of the prosecution was his complete vindication.

Independently of the personal annoyance and the professional damage sustained, in consequence of the groundless indictment, Dr. Forbes was compelled to incur, in defending his character, heavy expenses, amounting to nearly four thousand dollars. As the suit was instituted while he was acting, not in the capacity of a private teacher, but in the interest and service of a public institution and of the profession in general, it seems unfair that he should be compelled to bear this burden alone. It has been suggested by several members of the medical profession that some measures should be adopted to indemnify Dr. Forbes against the pecuniary loss sustained.

To effect this object, it has been thought best to appeal to the different County Societies of the State, soliciting their co-operation in this matter. If these Societies, or their individual members, acting in concert with the profession of Philadelphia, will contribute to the general fund

such amounts as they may see proper, it is probable that Dr. Forbes can be reimbursed. It is hoped that a very general subscription, of even small amounts, will testify to the feelings of the profession in this matter.

If this project meets your approbation, kindly give it your support in your County Society, where we hope the subject will be presented at an early date.

Contributions may be sent to either of the undersigned :

DR. D. HAYES AGNEW, 1611 Chestnut St.,
DR. RICHARD J. LEVIE, 1601 Walnut St.,
Committee.
DR. J. WILLIAM WHITE, 222 S. 16th St.,
Treasurer.

This appeal to the profession will, we hope, meet a prompt and satisfactory response. To allow Dr. Forbes to bear this burden alone would be most unjust. As we took occasion to point out at the time, his action throughout the whole history of the occurrence was not only correct, but praiseworthy ; and when a false sentiment based on false information pushed the charge to a decision in open court, it was in his favor, and vindicated him completely.

There is another aspect of the case to which we then alluded, and which also cannot fail to suggest itself to the reader of the above circular. It will be observed that Dr. Forbes incurred this unfounded charge and sacrificed a large sum in defending himself against it, "not in the capacity of a private teacher, but in the interest and service of a public institution."

Why has not that "public institution" paid this bill of costs? Is it poor? No; it is wealthy, probably having the largest income of any medical college in America.

Do the names of any of its officers appear on this appeal for the sum needed to protect one of its own instructors? Not one.

It may easily be guessed that there is a history beneath this action. Let not the position which belongs to them prejudice the cause which is here brought before the professional public. While primarily the duty of aiding Dr. Forbes rests on the institution to which he was attached, it now rests on the profession to which he belongs, and we ask for it prompt and liberal reception.

DYSPEPSIA A SYMPTOM OF KIDNEY DISEASE.

We desire to call special attention to the extract from a lecture by Dr. Da Costa, published on another page, because what it teaches is most important, and is well worthy of being carefully stored up in the mind, and kept before us in our daily work.

Derangements of digestion are very common in all organic diseases, but it seems that they are particularly liable to be present in the various forms of kidney disease, grouped together and generally known as "Bright's Disease."

We have known many cases that have lasted, no doubt, for years, and in which the only symptom that presented itself to the attention of the patient up to within a very short time of a fatal termination, was an obstinate "dyspepsia," that no drugs nor precautions in eating, nor hygienic measures of any kind, no matter how conscientiously carried out, could relieve. Whether the prolonged faulty digestion and consequent assimilation of imperfectly prepared nourishment has caused the changes in the kidney tissue, or whether the impaired action of the kidneys and the consequent retention of excrementitious matter in the system has caused the dyspepsia, or in other words, the relationship of cause and effect between the dyspepsia and the kidney disease, we do not know, and neither is it of much practical importance that we should know. One theory that has been advanced as to the etiology of Bright's disease, holds that owing to faulty preparation the blood albumen is really unfit to remain in the blood, it is excrementitious and must be removed, and that the irritation caused to the kidneys in performing this work, results in an inflammation and degeneration of their structure. If this be true, then we might reasonably suspect that the dyspepsia may act as a cause. But for our practical purposes, we say again, it makes no difference which is the cause and which the effect.

The point that we wish to make is that dyspepsia is frequently the only symptom or sign of chronic Bright's disease that makes itself manifest to the patient, and that when we are called

upon to treat a case of chronic dyspepsia, which baffles our skill and resists the treatment that *ought* to cure it, it will be in order to make a careful examination of the urine. It will unravel many a mysterious case, and help us much in our treatment.

METHODS OF STUDY OF INEBRIETY.

In spite of the enormous amount of discussion about temperance and intemperance, there is a sad lack of solid knowledge as to the causes and effects of inebriety. There has been too much sentiment, and too little cold, accurate observation on the matter. An attempt is now commenced by putting a series of questions to physicians, of a kind to elicit the information requisite to get at the truth.

These inquiries are put by the American Association for the Cure of Inebriates, which was organized in 1870 for the purpose of studying the nature and causes of inebriety from a purely scientific standpoint.

The purpose of these questions is to gather the practical experience and observation of leading members of the medical profession, as a basis for a more accurate knowledge of the nature and character of inebriety.

We believe our readers will be glad to see what they are. They run as follows:

What particular mental and physical changes have you noticed concerning the character and general health of the inebriate, that would suggest the idea of disease and the need of physical care and treatment?

Have you noticed any form or condition of inebriety that seems to be produced or is largely influenced by the kind of alcoholic drink used, or the work engaged in, or the food or climate, or any other unsanitary surroundings?

Can you give any facts from observation, bearing on the heredity of inebriety; particularly as to the presence of insanity, epilepsy, phthisis, inebriety, or other neuroses in the parents or relatives of inebriates?

Give cases with histories, if possible.

Have you seen any cases in which insanity or epilepsy either preceded or followed inebriety? If so, was it traced to the use of alcohol alone, or was it due in part, or in whole, to some inherited or acquired diathesis?

Can you give any history of inebriates whose drinking dated from or was influenced by head injuries, sunstroke, syphilis; or could be traced to mental shock, disease or injury of any kind; also to over-work, nervous exhaustion, anemia, and any specific causes which broke down or injured the system?

Have you noted any distinction between the different

forms of inebriety, such as irregular, continuous, or periodical inebriety? State any facts you have noticed which relate to the periods and forms of drinking.

Illustrative cases concerning any of these inquiries will be welcome, and a full expression of opinion from observation and experience is urgently requested.

The Secretary of the committee, to whom answers should be addressed, is Dr. T. D. Crothers, Hartford, Conn.

It will be seen that the investigation is directed to the classification of the varieties of inebriety; and that the etiology of the condition is to be studied from other points of view from those heretofore received. The necessity of this is obvious. Even among the better educated of the medical profession there remain some who are unwilling to look upon inebriety as a disease, but persist in regarding it as a crime, to be treated rather by religious measures than by therapeutic agents.

We have little doubt but that the many questions relating to intemperance will be considered in a more efficient manner by such investigations as the above.

ANTI-VIVISECTION.

It is with regret that we have to chronicle the appearance of the anti-vivisection fanaticism in our midst.

A meeting was recently held in this city for the purpose of arousing the interest of the public in the question, and to our surprise it was attended by physicians who made speeches in behalf of the movement.

Tenderness toward the brute creation, sympathy with suffering animals, and a desire to prevent the unnecessary infliction of pain, is a sentiment well worthy of the heart of man, and one that is deeply implanted in the being of every gentleman. But to any one who realizes how absolutely necessary to the progress of medical science is the practice of vivisection, it seems almost inconceivable that any one would wish to prohibit it.

We fully agree with those who would restrict its use within certain limits, limits that would insure the saving of ten thousand pains to humanity for every single pain inflicted on a lower animal; as, for instance, requiring a certain au-

thority, as a license to practice vivisection, procurable (without expense) only by those who can furnish satisfactory evidence that their physiological studies have progressed sufficiently far to make it reasonably sure that the results of their experiments on animals will redound to the good of mankind.

Without going into details, let us ask ourselves how much we would know about physiology to-day were it not for vivisection; and let the answer that must come to the mind of every unbiased person serve as his argument against and condemnation of the anti-vivisection excitement.

To prohibit the inevitable is only to make it still more inevitable, if possible. That the ardent student of physiology *will* experiment upon the lower animals, is just as certain as that the ardent lover of alcohol *will* drink whisky, prohibit it as much as you choose. Therefore, let these well-meaning persons avoid putting a premium upon lawlessness, by endeavoring to prohibit that which *will* be done in spite of all prohibition.

NOTES AND COMMENTS.

Sudden Death after Quinine.

Especially in cases of typhoid fever, it has often been contended that large doses of quinine are responsible for sudden deaths in that disease, when administered to a typhoid patient with a weak heart. This observation was originally made by Hardy. Laborde (Schmidt, *Jahrb.* 28, 1883,) has investigated the effect of quinia on the heart to determine the truth of Hardy's assertion. He found that large doses of quinine may cause cessation of the action of the heart in a double manner: by hyper-irritation (hyperexcitation inhibitoire), or by functional exhaustion in consequence of the ataxic phenomena or the arrhythmia and of asystoly.

L.'s experiments, which have been instituted with great care, excluding every possible error, seem to prove, indeed, that there is a connection between the sudden deaths in typhoid and other low fevers, by heart or respiratory syncope, and large doses of quinine. The effect may be produced in a double manner, either by the heart itself being suffering (as usually is the case in these fevers), or by affection of the kidneys, when, in consequence of diminished excretory power of the

latter the excretion of the quinine is retarded, and its dangerous effect upon the heart is increased thereby.

What has been said of quinine, has reference also to cinchonin, only, that in this case the primary spasmodic effect of the latter influences the function of the heart in such a way as to increase the ataxic disturbances and the tetanizing effect to their maximum, without calculating the grave disturbances in connection therewith, which generally cause a mechanical, mostly fatal, asphyxia. The administration of cinchonin instead of quinine, or the adulteration of the latter by the former (in Paris hospitals such has been discovered up to 40 p. c.), is by no means indifferent.

Apropos of these investigations, L. draws the attention to another, yet more dangerous, adulteration of quinine, viz., that with cinchonamin, an alkaloid which differs from cinchonin by being composed of two atoms more water, and by being very much cheaper, and which is found in combination with cinchonin (never with quinine nor cinchonoidin), especially in the *remija purdiana*. Into a fat rabbit a hypodermic injection was made of four grains of sulphate of cinchonamin. As if struck by lightning, the animal dropped on its side, stretched once its legs, and was dead; while after an injection of the same quantity of cinchonin death would not have taken place under less than one hour and a half, and then under symptoms of violent epileptiform convulsions.

Certainly this fact proves the great difference in the effect of these alkaloids. It is the old story. Some authors report never to have met with fatal cases in the application of certain drugs; others, equally trustworthy, insist upon their having done so. It would seem almost as if in such cases we may safely say, that the first, perchance, had procured a pure, the last an adulterated drug. It is another lesson for us to be careful of whom we buy our remedies, and never to endeavor to buy the cheapest, but always the best and purest article. To be sure, a chemical analysis will detect the swindle: but this discovery is sometimes exceedingly difficult for the expert chemist; how much more—aside from the inconvenience—must it be for the practicing physician, who cannot be *master of a sister science*.

Nerve-Stretching in Locomotor Ataxia.

Prof. W. Stokes, of Dublin, has resorted to this procedure in two cases with rather satisfactory results. In the first case the success was sufficiently encouraging. The operation was followed by the restoration of plantar sensibility, by

marked diminution both in frequency and intensity of the shooting pains, and by temporary relief from vesical irritability. There was no return, however, of the patellar reflex, no improvement in locomotive power, and no change in the muscular incoördination. The force employed was estimated roughly at about eight or ten pounds. Antiseptics were used, and the wound, though slow in healing, was always aseptic. In the second case both sciatic nerves were stretched, and very marked and abiding were the beneficial effects, although "severe constant pains at the situation of the operation, accompanied by spasmodic contraction of the muscles of the leg, were complained of by the patient for some hours after the operation." The lightning pains were absolutely abolished; there was temporary increase of power in the legs, and the urinary troubles were abated. Professor Stokes remarks that the *rationale* of the treatment remains as yet unexplained, although he admits a possible solution of the problem based on the observations of Drs. Brown-Séquard and Bastian, that the operation produces "a certain amount of vaso-motor paralysis resulting in vascularity and increased temperature, and that these may lead to improved nutrition of the affected part." Professor Stokes differs from Mr. Marshall as to the advisability of using a dynamometer to estimate the force exerted, since he has decided to employ it in future operations. Professor Stokes' experience leads him to the conclusion that a force of ten pounds is sufficient for the sciatic nerve. Mr. Marshall thinks one of thirty pounds is a very safe one. Both assert eighty-eight pounds, the maximum fixed by M. Artant, to be replete with danger.

Iodide of Potassium an Anti-Galactagogue.

In the *Brit. Med. Jour.*, January 5, 1884, Dr. I. Jenner Verrall writes: "In a recent case of excessive secretion of milk after weaning, I have found the above drug of great service. The child had been weaned more than a week, and the breasts were very large, hard, and tender. Belladonna and aconite, applied freely, together and singly, had failed; this, although combined with firm compression of the breasts by a bandage, and the administration of salines and purgatives—a form of treatment generally successful. Ten grains of iodide of potassium were taken three times a day, and decided relief was obtained after the fourth dose. In all, 160 grains were taken, and then all trace of swelling had disappeared. With each dose I gave half a grain of quinine, as I always do when giving the iodide in rather large

doses. There was no symptom of iodism. Before taking the drug internally, my patient had used the iodide and soap liniment for two days without much benefit, and continued to use it till treatment ceased.

"As long ago as 1858, Roussel, and, in 1861, Delmas, recommended the iodide, and were supported by Dr. Morris, of Cheltenham, in 1864. Dr. Dolan, however, in the *Practitioner* of 1881, quotes Dr. Morris, but reports that the drug, given by himself in larger doses than Dr. Morris had used—namely, fifteen grains against a drachm—had produced no effect. At the time of my case, I had not seen these papers, and was led to use the iodide solely on account of its known action on glandular tissues. I could find no mention of it in Ringer, Woods, Bartholow, or Phillips."

Salicylic Acid a Cure for Tic Douloureux.

We frequently meet in our practice cases of tic douloureux, that often so exceedingly painful neuralgia of the fifth nerve, where an operation seems to promise the only radical cure. If we hear of a remedy which is said to have the same effect as the surgical interference, we become doubtful; but if no less reliable an authority than Prof. Nussbaum (*Munich, Aertzl. Intelligenzbl.*, 38, 1883,) assures us of the fact, our hope increases. Recently a number of such cases had been sent to N. for the purpose of having the operation performed, and after a number of carefully instituted experiments, this great surgeon recommends a trial with salicylic acid before proceeding to stretching or to resection of the nerve. In all the recently-sent cases he first tried this remedy, and he found it in every one a radical cure; not only a palliative effect, but really an utter disappearance of the painful disease was the result in every case. Especially in cases of rheumatic nature, N. is positive of having discovered in salicylic acid a specific for tic douloureux. He administered the drug in the following manner:

R. Acidii salicylici, 0.2,	gr. 3½.
Sodii salicylatis, 2.0,	gr. 32.
M. ft. pulv.	

Within 24 hours the patient takes from 4 to 6 of such powders.

Pulverized Vaccine Matter.

An important discovery by Dr. Reissner promises to do away with all scarcity of vaccine matter in the future. It offers few difficulties, and every country physician can provide himself with a practically unlimited quantity of the purest animal vaccine virus, at a nominal expense.

A calf is vaccinated with pure virus, and after five full days, the pustules are taken off with a pair of forceps, and shaved with a lancet and pressed so as to obtain all the fluid lymph contained. This lymph is spread on glass plates and placed in a sulphuric-acid exsiccator, where it remains one or two days. It is then taken out, pulverized in a mortar, and replaced in the exsiccator till wanted, when it is mixed with a little water or glycerine.

Thus prepared, the virus from one calf will vaccinate 2,000 to 3,000 persons. The calf is as well as ever in a few days, and the physician is provided with the purest of bovine virus for an indefinite period.

The National Board of Health.

Our contemporary, the *Boston Medical and Surgical Journal*, is hard on this respectable but prematurely exhausted body. It says:

"In any other country than the United States, the resignation of its members would have been placed in the President's hands. * * * Thirty pages out of the one hundred and two of the report before us [are] devoted to the old quarrel with the Louisiana Board of Health, and which probably few people are interested to hear now."

The *Journal* advises the National Board of Health to confine their energies to internal matters, and to work in harmony with the Marine Hospital Service, who may be given the quarantine. They have, however, a field for themselves in the study of statistics and the abstract branches of medical science, as we pointed out a year ago. These would return better fruit than quarrels about precedence.

Mullein Leaves in Phthisis.

A correspondent of long experience in the profession writes us:

"Having seen the mullein referred to as a remedy for phthisis, I am led to tell you that I first saw the remedy suggested in the M. AND S. REPORTER about 1855, to be smoked in a pipe. At that time I was a young practitioner in Sussex county, Del., and the wife of the landlord with whom I boarded belonging to a family of consumptives, and having repeated attacks of catarrh with profuse expectoration, was thought to be in great danger of the disease. She was then about 35 years old, and quite a smoker. I recommended her to get mullein and dry it, and mix it with her tobacco for smoking. From this she derived great benefit, and kept up the practice for many years. Her death occurred some years since, but I do not

know the cause. I have recommended the use of the mullein to many others, but I have never known it followed up so well as in the case of the lady mentioned. I feel sure that her life was prolonged by its use."

Sulphuric Ether as an Anæsthetic.

No other anæsthetic than sulphuric ether is used in the hospitals of Naples, Lyons, and Geneva. Dr. J. R. Comte, of the last-named city, has recently published some facts gathered from the three named.

The ether must never exceed a specific gravity of 0.725 at 15°C., and must have no acid reaction and no trace of fusel oils.

With such, 100 cubic cent. will produce anæsthesia in an average of six minutes. The ether must be inhaled in full doses and concentrated. The pulse rises to 110-140 per minute. The temperature invariably falls, the urine diminishes in quantity and falls in specific gravity. Small injections of morphia are occasionally beneficial to control excitation. Nothing special is recommended against the vomiting.

Intestinal Worms a Cause of Invagination.

From the *Rev. Med.* we learn that in a number of autopsies practiced upon animals dying with symptoms of intestinal occlusion, M. Mégnin found in a certain number that the obstruction was due to intussusception. In nearly all these cases he found a large number of ascarides in the intestine, and thought that the irritation caused by their presence had induced such energetic peristaltic movements as to force a portion of the small intestine through the cæcal valve. The usually accepted causes of invagination are defective hygiene and enteritis, and it is probable that the intussusception in these cases was referable to an enteritis set up by the presence of large quantities of the lumbricoids, rather than to simple irritation.

The Influence of Spices on Digestion.

Hasson has been making some experiments on this question, which he publishes in the *Wiener Med. Blät.* He has carried out his experiments with artificial gastric juice, in which he has placed meat which had lain for four days in wine, vinegar, oil, charcoal, and common salt respectively. The meat which had been immersed in white wine dissolved the most rapidly, that in vinegar, oil, and charcoal just as quickly as fresh meat, while the salt meat was much more difficult to dissolve. He then experimented on the influ-

ence of salt, and found that small quantities hastened digestion, but that a larger amount retarded it. Acetic acid seemed to hasten digestion in exact proportion to the dose.

Relations of Menstruation to Ovulation.

The recent researches on this subject by Prof. Leopold (in the *Archiv für Gynækologie*) result in showing that ovulation may take place without menstruation. In fact, the latter does not directly depend on the former, but only indirectly. The immediate exciting cause of the congestion which leads to the menstrual flow is not the expulsion of the ovum, but the formation of new cells in the ovary, which leads to a general congestion of the genital tract and may or may not result in the ripening of an ovule. Prof. Leopold, however, acknowledges that the facts obtained are not sufficient to establish a positive theory.

Helenin as an Expectorant.

A late issue of *El Siglo Medico* contains an article by Dr. F. Valenzuela, urging the value of helenin in bronchitis (chronic), broncho-pneumonia, and tuberculosis, for controlling the cough and facilitating expectoration. In whooping-cough he has also found it "surprisingly efficient." It is not a narcotic, and both appetite and digestion improve under its use. The dose he gives is five drops of the tincture three times a day—but he neglects to add the strength of the tincture employed.

Nervous Dyspepsia.

We had recently occasion to say a few words about this condition, and it affords us pleasure now to note that Gallerani (*Rivista Clinica*) has had some experience with a similar condition. In his case the trouble was of two years' duration, and he cured it with belladonna. He gave two-fifths of a grain of extract of belladonna divided into two doses, one to be taken an hour before luncheon, and the other an hour before dinner, during the first three days of treatment. This dose was increased to three-fifths of a grain daily during the last four days.

Digitalis in Dropsy from Heart Failure.

Two cases reported in the *Canada Med. and Surg. Jour.*, January, 1884, afford excellent examples of the good results to be obtained from digitalis in the dropsy of heart-failure. In the first case, the man's condition was desperate. On three several occasions he was rescued from a state of extreme danger and great suffering by prompt treatment,

and was restored for a considerable time to comparative comfort and activity. The autopsy showed absence of any disease of the valve curtains, but great enlargement of the auriculo-ventricular opening. One drachm of infusion of digitalis with bitartrate of potash and spirits of chloroform were given thrice daily.

Water Dressings for Wounds.

Listerism means cleanliness; hence, when Dr. J. J. Larkin gives a thrust at Listerism in the *Pt. Wayne Jour. Med. Sci.* for January 1884, delicate though it is, and then goes on to describe his cold water dressing, it seems rather paradoxical, since his recommendation really embodies Listerism, because it advocates cleanliness. He has had most satisfactory results in incised wounds and amputations, with dressings of cold water with *one-half per cent. of carbolic acid*. Cold contracts the blood and absorbent vessels, prevents swelling and pain, and consequently inflammatory actions; water soothes, cleanses and facilitates drainage; rest is the only condition remaining to complete the best plan for recovery.

Fatal Traction on the Umbilical Cord.

In view of the case reported to the *Med. Record* by Dr. George Huntington, it will be well to give the stern injunction, "Hands off," to the army of officious and meddlesome women who are always on hand at a country accouchement. He was called to a woman in labor, and when he arrived found her dead. The child had been delivered spontaneously, and some fussy woman had pulled on the cord until she had inverted the uterus, and the woman died from hemorrhage.

Electricity for Ovarian Pain.

From the *Rev. de Therap.*, we learn that Mr. Apostoli makes use of a faradic stream of high tension, applied to the uterus, either by means of a double uterine electrode, or of an electrode pushed into the vagina, the other being placed on the hypogastrium. The stream must never be powerful enough to excite pain; the sittings must generally be repeated daily, and last about ten minutes.

A Cause of Blindness.

In the course of an article in the *Am. Practitioner* for January 1884, Dr. E. Williams says that in endocarditis or arteritis, and in women exhausted by puerperal hemorrhage, a coagulum may drift into the main artery of the retina and cause in-

stantaneous blindness. Recovery of sight after such accident is almost impossible.

Carbonic Acid in Whooping Cough.

Inhalations of carbonic acid are recommended by several authorities in the *Rev. de Therap.*, December 15, 1883. It is obtained from an apparatus for making Seltzer water, and was slowly inhaled through a long rubber tube placed at the nasal orifices.

NEWS AND MISCELLANY.

New York State Medical Society.

The seventy-eighth annual meeting of this Society was held in Albany February 5, 6, and 7. The Inaugural Address was delivered by the President, Dr. Alexander Hutchins, of Brooklyn. Dr. Wesley M. Carpenter read a very interesting biographical sketch of Dr. J. Marion Sims, after which Dr. J. P. Creveling, of Auburn, read a short paper on "Double Hare Lip." The following papers then followed: "Two Unusual Cases in Obstetrical Practice," by Dr. W. C. Wey, of Elmira; "Prophylaxis of Summer Complaint in Infants," by Dr. David Little, of Rochester; "Neuber's Deep Canulization in Amputation of the Female Breast," by Dr. A. G. Gerster; "An Operation for Correcting Deformity of the Auricle," by Dr. O. D. Pomeroy, of New York; "Poisoning by Potassium Chlorate," by Dr. George B. Fowler; "The Establishment of Hospitals in Small Cities," by Dr. Parker, of Poughkeepsie; "A New Method of Partial Extirpation of the Cancerous Uterus," by Dr. Van de Warker, of Syracuse; "The Value of Electricity in Diagnosis," by Dr. L. E. Felton, of Potsdam; "Congenital Lipoma," by Dr. A. Jacobi; "Orbital Cellulitis," by Dr. T. R. Poole; "A Plea for the Pharmacopoeia," by Dr. Laurence Johnson; "Operations for Closure of the Hard and Soft Palate," by Dr. Vanderveer, of Albany; "Sympathetic Ophthalmia," by Dr. David Webster, of New York; "The Value of Horse-hair as a Means of Drainage," by Dr. Daniel Lewis; "Dysmenorrhœa, its Treatment by Dilatation," by Dr. W. W. Potter, of Buffalo; "Two Cases of Rupture of the Heart, with Pathological Specimens," by Dr. T. H. Squire, of Elmira; "Biographical Sketch of James Rushmore Wood, M. D., LL. D.," by Dr. Frederick S. Dennis; "Biographical Sketch of the late Dr. G. W. Bradford," by Dr. E. C. Green, of Homer; "Biographical Sketch of the late Dr. J. F. Jenkins," by Dr. G. J. Fisher, of Sing Sing; "The Medical Society of the State of New York in its Relation to Science," by Dr. E. Harris, of Albany; "Biographical Sketch of Dr. Jas. S. Bailey," by Dr. F. C. Curtis, of Albany; "House Sanitation, as It Is and as It Should Be," by Dr. W. F. Sheehan, of Rochester; "The Mechanical Treatment of Hip-joint Disease," by Dr. Milton J. Roberts, of New York; "Synovitis of the Knee and Ankle Joints," by Dr. A. M. Phelps, of Chateaugay; "Morbid Drowsiness and Somnolence," by Dr. C. L. Dana, of New York; "The

Management of Face Presentations," by Dr. E. L. Partridge, of New York; "Arsenic and Digitalis in Phthisis," by Dr. A. Jacobi, of New York; "Two Cases of Poisoning by Tansy," by Dr. W. Woodward, of Big Flats; "Sympathetic Serous Iritis," by Dr. Webster, of New York; "Forster's Method of Ripening Cataract," by Dr. Mitten-dorf; "Spontaneous Pyæmia," by Dr. J. B. Todd, of Parish; "Care and Preservation of Medical Pamphlets," by Dr. J. G. Fisher, of Sing Sing; "Strangulated Hernia, Five Cases Treated by Operation," by Dr. J. Chapman, of Medina; "Notes on the Treatment of Diseases of the Digestive Organs," by Dr. F. A. Castle, of New York; "Hay Fever," by Dr. J. O. Roe, of Rochester; "The Cure of Spinal Caries without Deformity," by Dr. M. Josiah Roberts, of New York.

After some discussion, the question of repealing the new code and going back to the code of the American Medical Association was put to vote, which resulted in 105 in favor of the repeal and 125 against it; thus dooming the New York State Society to another year of professional ostracism.

Dr. A. Jacobi, of New York, offered a resolution calling the attention of Congress to the importance of the speedy passage of the bill providing for the erection of a fire-proof building for the medical department of the army. The resolution was adopted, and it was ordered that it should be sent to the proper committee, attested by the seal of the Society and the signatures of the President and Secretary.

The Committee on Prize Essays reported that there had been two essays submitted:

1. "Tuberculosis of the Breast," by Dr. Ghislandi Durant, of New York, for which the Cash Prize was awarded.

2. "Consumption," which was thought worthy of publication.

Dr. Powers, of Ontario, Canada, made some remarks in regard to an Act regulating the practice of medicine, recently passed in Ontario. The Act requires an examination previous to matriculation, four years of study at a medical college, and the examination by a board independent of all teaching bodies. No degree from any part of the world will license a person to practice in Ontario.

Dr. Jacobi, of New York, from the Committee to Coöperate with the Society for the Prevention of Cruelty to Children, reported that a hospital for diphtheria and scarlet fever had been organized in New York, and would soon be ready for occupation. The committee offered the following resolution, which was adopted:

Resolved, That the State Medical Society deeply regrets the failure of the Legislature last year to enact the law proposed by its committee for the protection of children engaged in factory work, and respectfully commends the subject to the attention of the present Legislature, with the hope that definite action will be had in the matter, which is of grave importance and deep interest to all humane persons.

The Nominating Committee then presented the following report, which was adopted:

President.—Dr. B. F. Sherman, of Ogdensburgh.
Secretary.—Dr. William M. Smith, of Syracuse.
Treasurer.—Dr. Charles H. Porter, of Albany.
Censors.—*Southern District*: Drs. F. A. Castle,

Geo. H. Fox, D. Webster. *Eastern District*: Drs. E. D. Fergusson, N. L. Snow, LeRoy McLean.
Middle District: Drs. A. Churchill, J. K. Chamberlayne, Frazer. *Western District*: Drs. T. F. Rochester, B. L. Hovey, T. Dimon.

Committee on Ethics.—Drs. A. Jacobi, A. Mathewson, C. E. Whitbeck.

Honorary Member.—Dr. William G. Bronson, of Connecticut.

Adjourned.

The Veterinary Department of the University of Pennsylvania.

This new department is now organized. The faculty includes William Pepper, M. D., LL. D., Provost of the University and *ex-officio* President; Rush Shippin Huidekoper, M. D., V. S., Dean, Professor of Internal Pathology, and *pro tempore* Professor of Veterinary Anatomy; James Tyson, M. D., Professor of General Pathology and Morbid Anatomy; Horatio C. Wood, M. D., LL. D., Professor of Materia Medica, Pharmacy, and General Therapeutics; Theodore G. Wormley, M. D., LL. D., Professor of Chemistry and Toxicology; Harrison Allen, M. D., Professor of Physiology; Joseph T. Rothrock, M. D., B. S., Professor of Botany; Andrew J. Parker, M. D., Ph. D., Professor of Comparative Anatomy and Zoölogy; Robert Meade Smith, M. D., Professor of Comparative Physiology; ———, Professor of Surgical Pathology and Obstetrics; Adolph W. Miller, M. D., Ph. D., Demonstrator of Pharmacy; Henry F. Formad, M. D., B. S., Demonstrator of Pathology and Morbid Anatomy.

The course of study extends over three years, the year beginning on October 1 and ending on June 15. The requirements for admission to this Department are the same as for the Department of Medicine. The studies are for—

First Year.—Chemistry, Materia Medica and Pharmacy, Physiology, Histology, Botany, Zoölogy, Veterinary Anatomy, and Forging.

Second Year.—Medical Chemistry, Physiology, Therapeutics, General Pathology and Morbid Anatomy, Veterinary Anatomy, Surgical Pathology, Internal Pathology and the Contagious Diseases, Botany, and Zoölogy.

Third Year.—Therapeutics, General Pathology and Morbid Anatomy, Surgical Pathology and Operative Surgery, Internal Pathology and the Contagious Diseases, Sanitary Police, Obstetrics, and Zoötechnics.

In the second year the student will attend clinics, and will serve as aid in the hospital; in the third year, he will be placed in charge of sick animals, and be required to prepare clinical reports and make autopsies. He will also make regular visits to breeding and dairy farms and to slaughter-houses, in order to familiarize himself with the races of animals, the economical means employed in their care, and the varieties of butcher meat.

Examinations will be held at the close of each year and at the end of the course. All these examinations must be passed satisfactorily before the student can be registered as a candidate for the degree.

Graduation.—Upon completing satisfactorily the full course of study, the student receives the degree of Veterinary Surgeon (V. S.), upon the

same conditions as those on which the degree of Doctor of Medicine is conferred.

A handsome amphitheatre and large rooms for dissection and laboratory work have been erected, and the stables requisite for hospital use will be finished and occupied before the opening of the department, in September, 1884.

A National Pharmacopœia for the United States.

On January 8, 1884, Mr. Randall presented the following bill to the House of Representatives:

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,

That the Secretary of the Treasury shall, as soon as practicable, detail two officers of the Marine Hospital Service, and the Secretary of War shall detail two officers of the Medical Staff of the Army, and the Secretary of the Navy shall detail two officers of the Medical Staff of the Navy, for the duty of compiling and preparing a pharmacopœia, which shall be known as the *National Pharmacopœia of the United States of America*, and shall be held and accepted as the standard for the purveying, compounding, and dispensing of drugs or medicinal agents, and shall be taken as authority in the Treasury Department on all questions arising under the tariff laws of the United States with regard to the nomenclature, description, and purity of drugs or remedial agents, and shall further be received as evidence in the United States courts. And the matters contained in the said pharmacopœia shall be free for use by all authors and commentators for the benefit of the medical and pharmaceutical professions and of the community at large; and it shall not be lawful for any one to reprint and publish the said pharmacopœia as a whole.

Sec. 2. That the medical officers detailed as above provided shall invite the American Medical Association and the American Pharmaceutical Association, at their next annual meetings, to form committees of not more than three members from each of the said Associations, which committees, if so appointed, may cooperate with the above-named medical officers in the preparation of the said pharmacopœia, forming a board which shall have power from time to time to add to its number as may in its judgment be necessary, and which shall elect a chairman and secretary, and adopt such rules as it shall see fit for the expediting and perfecting of the said pharmacopœia, which, when completed, shall be printed under the supervision of the said board; and an edition of not less than five thousand copies shall be printed, for use in the several departments of the Government of the United States; and copies may be furnished to private persons in accordance with the provisions of section thirty-eight hundred and nine of the Revised Statutes.

Sec. 3. That for the purpose of defraying the necessary expenses of preparing the said pharmacopœia, the sum of five thousand dollars is hereby appropriated out of any moneys in the treasury not otherwise appropriated, and the same shall be disbursed under regulations to be prescribed by the Secretary of the Treasury.

Sec. 4. That the said pharmacopœia shall be revised once in ten years, upon the plan embodied in this Act.

Pharmaceutical Notes.

Jensen's Crystal Pepsin.

The knowledge of the value of this variety of pepsin is rapidly extending. Recently the United States Marine Hospital Service has ordered three kilos of it at once, to be put up in 2.5 gramme bottles. Dr. Jensen has devoted many years of close attention to perfecting his product, and it now stands with the very first in its line.

Nitrogenized Iron.

This ferruginous product, prepared by Chapman, Green & Co., Chicago, ranks as one of the best of chalybeates. It is palatable and efficient.

Bromidia and Papaine.

The pharmaceutical preparations of Battle & Co., of St. Louis, are in no sense secret preparations. The full formulæ are open to the profession. Their claim to favor rests on the exceptional purity of the constituents employed, uniformity in composition, agreeable flavor, and judicious proportion. We have been using for some time the two above-named, and they evidence the justice of these claims.

The Philadelphia Clinical Society.

The Northern Medical Association of Philadelphia reorganized at the College of Physicians on the evening of January 26th, as the Philadelphia Clinical Society. A large number of new members were enrolled, and the following officers elected for the ensuing year:

President—Henry Beates, Jr.

First Vice President—E. E. Montgomery.

Second Vice President—Hannah T. Croasdale.

Corresponding Secretary—J. E. Richardson.

Recording Secretary—J. G. Heilman.

Reporting Secretary—G. Betton Massey.

Treasurer—L. Brewer Hall.

Censors—A. S. Barton, S. N. Troth, Albert H. Smith, James B. Walker, and Henry Rihl.

To Prevent Horses from Slipping.

From the *Med. Press* we learn that Mr. C. C. Baird, of the Dick Veterinary College, Edinburgh, has invented an india-rubber frog-pad for fitting into the heels of the shoes of horses, with the view of preventing the animals from slipping and falling. The invention is exceedingly simple, and will be of great value to medical men and others who drive horses, especially on asphalt, and in frosty weather. The pad can be removed in the evening and replaced in the morning. A set of pads is expected to wear out two sets of shoes. The trial of the invention has fully borne out the statements of the inventor as to the merits of the apparatus.

A New Medical Society in New York State.

On February 6, a meeting of the adherents of the National Code of Ethics was held in Albany, and the New York State Medical Association was organized. The following officers were elected:

President—H. D. Didama, M. D., of Syracuse.

Secretary—E. D. Fergusson, M. D., of Troy.

Treasurer—John H. Hinton, M. D., of New York.

Dr. Austin Flint, Jr., proposed New York as the next place of meeting, which was adopted. It was resolved that the time of meeting should be the third Tuesday of November.

American Pork in France.

The French Academy of Medicine, in reply to the questions propounded by the Minister of Commerce, relative to the importation of pork, says: First, that the symptoms of typhoid trichinosis are so dissimilar from all others that they never can be mistaken, and second, that the importation of foreign salt pork may be fearlessly authorized by the French Government, as it has been clearly proved that no danger to the public health has been caused by such importation.

Sacrificed to Duty.

From a foreign exchange we learn that Dr. G. A. Popow, one of the assistant physicians of Prince Peter von Oldenburg's Children's Hospital, while engaged in examining the throat of a bad case of diphtheria, received on his lips and face some of the secretions from the child's mouth. In spite of the most careful cleansing, he was seized next day with shivering and the first symptoms of an attack of diphtheria, which within five days proved fatal.

The Sewer System of Denver.

Colorado, and Denver (as its chief city), has become so much of a health resort that it has become very essential that its sanitary arrangements should be well looked after. The difficulty about its water supply has been overcome by the boring of artesian wells, which furnish an abundant supply of most wholesome water, and we are pleased to learn from the *Denver Medical Times* that a most efficient system of sewerage has been introduced.

A Ventilated Quilt.

The *Lancet*, December 29, 1883, tells us that a Mr. Pocknell has invented some kind of a ventilated quilt, that, while it preserves the warmth of the body, yet allows of ventilation. Our authority does not seem to have a very definite idea of the nature of this invention, but believes that "it consists in a system of perforations which are filled in with some substance that allows the vapor to escape."

Items.

—Leprosy and elephantiasis are common and widespread throughout Mexico.

—Dr. J. Morrison, of the *Nautical Almanac* office, Washington, D. C., has been elected a Fellow of the Royal Astronomical Society of London, England.

—Dr. Frank H. Hamilton's work on *Fractures and Dislocations* has recently had a sixth revision and translation into French at the hands of Dr. G. Poinset.

—M. Pasteur's Cholera Commission is to be honored by the nomination of two of its members, M. Straus and M. Roux, as chevaliers of the Legion of Honor.

—The Chamber of Commerce of Cincinnati is said to have voted to memorialize Congress to take prompt retaliatory measures in regard to the prohibition of the importation of American pork into France and Germany.

—One of the members of the Louisiana State Board of Health, Dr. Formento, has been nominated a corresponding member of the *Société d'Hygiène Publique*, of Bordeaux.

—The heaviest human brain observed thus far is said to have been that of the Russian poet, Turgeneff, who lately died in Paris. It is reported to have weighed 2,012 grammes.

—Important lesson to all writers, as given by Dr. Billings, U. S. A.: 1. Have something to say. 2. Say it. 3. Stop when you have said it. 4. Give a proper title to what you have said.

—At the recent examinations for *externes* to the Paris hospital, three women physicians passed successfully. There were 254 candidates. Madam Sarrante passed sixth, and Madame Chopin one hundred and forty-second.

—Holmes calls Ricord "the Voltaire of pelvic literature—a skeptic as to the morality of the race in general, who would have submitted Diana to treatment with his specifics, and ordered a course of blue pills for the vestal virgins."

—The abolition of chaplaincies at the Paris hospitals has excited the indignation of the Archbishop of the city, who advises the faithful not to send the sick to the hospitals, but to organize a system whereby they may be treated at home.

—The Senate Committee on Commerce is reported to have acted favorably on an amendment to the shipping bill providing for the abolition of the present system of supporting the marine hospitals by a tax on sailors, and throwing the expense directly on the government.

—It is claimed that many letters went to the Dead-Letter Office because of the inability of color-blind persons to recognize the difference in color between red and green. This is obviated by the law which has just gone into effect, of having but one denomination and a uniform rate of letter-postage.

QUERIES AND REPLIES.

M. D., of Pa.—You will find the full text of the Act to regulate the practice of medicine in Pennsylvania in the *MEDICAL AND SURGICAL REPORTER*, vol. xlv., p. 502. It will answer the questions you put.

A Correspondent requests those of our readers who have given some special attention to the treatment of asthma to communicate their most satisfactory methods through the columns of this journal. We second his wishes.

Dr. S. W. D., of Va., asks the experience of physicians on the use of carbolic acid, hypodermically, in hemorrhoids. He observes that some writers commend it, while Allingham and others say it is useless. We shall be pleased to publish replies.

Dr. K., of S. C.—We take a special interest in developing our knowledge of indigenous materia medica, and will gladly publish any observations in that line.

DEATHS.

SHRADY.—In New York, January 15, 1884, Jeannie Lookhart, wife of Dr. John Shrad, and daughter of Lucinda and the late Walter Sammis.

SWARTZLANDER.—February 6, 1884, Susan M., wife of Dr. Frank Swartzlander, in the thirty-second year of her age.

PROOF THAT HUMAN MILK CONTAINS ONLY ABOUT ONE PER CENT. OF CASEIN; WITH REMARKS UPON INFANT FEEDING.

BY ARTHUR V. MEIGS, M. D.,

Physician to the Pennsylvania Hospital and Children's
Hospital, of Philadelphia.

(Continued from page 197.)

There are objections to such a belief; it has been already shown that human milk contains only one-third the amount of casein that exists in cows' milk; and there is a further important difference, which Biedert also appreciates, that human milk is always alkaline, while, on the contrary, cows' milk is acid. A coagulum, therefore, produced in a solution which is relatively so concentrated as is the case in cows' milk, and further in a fluid which is acid in reaction, is a very much denser and larger one than can be had from the relatively weak solution in human milk; and it is quite possible, therefore, that the difference may be owing to the different degrees of concentration, and the difference of the fluid media in which the casein is held; it cannot, therefore, yet be conceded that Biedert has absolutely demonstrated that the two caseins are chemically and physically different, although he has brought many strong arguments to bear. It is impossible to decide with certainty about casein in all its relations, while as yet it is not even known whether it is a simple or compound substance. Its solubility or insolubility after it has once been precipitated depends in great part upon how the original coagu-

lation was effected, and whether or not it was thoroughly dried. If casein is once thoroughly dried for a good many hours at 100° C., it becomes absolutely insoluble in water, and will not dissolve even in a strong solution of caustic soda. Lehman (Physiological Chemistry, Cavendish Society Translation, vol. i, p. 378) says: "I believe that the jelly-like coagula of women's milk are more dependent on the alkaline state of the fluid than on any peculiarity in the casein; at all events, I have found that women's milk, when acid, yields a much thicker coagulum than when alkaline, and cows' milk, when alkaline, a much looser coagulum than when acid—facts of the highest interest and value in relation to dietetics."

Whatever may finally be decided about casein—whether those of cows' and human milk are as different as Biedert believes he has proved, or whether they are nearly alike, the difference being merely that the quantities are not the same and the containing fluid media different—what most concerns the subject in hand is the relatively small quantity which exists in human milk; for it shows conclusively that in a food for infants, the amount of casein in cows' milk must by some means be reduced to equal the amount in human milk. The correct conclusion of Biedert, that not more than 1 per cent. of cow casein should be present in a food for infants, is the more surprising as he arrives at the opinion from a totally different reason from the true one, that human milk contains only 1 per cent. (See table, page 226.)

Although Biedert's conclusions are very instructive, as he arrives at them from clinical experience; and surprisingly correct in many respects, he goes astray in assuming an incorrect

										Average from the 17 . . .	16.396

The human milk average is the result of ten analyses made. Eight separate analyses were made of the milk of different women; on another occasion, equal quantities of milk were taken from twenty-seven (27) women, and a portion of this analyzed; on a third, equal quantities of milk were taken from eight (8) colored women, and this subjected to analysis.

standard of the average composition of cream. The estimate of Hoppe, which he assumes to be correct, places the amount of casein too high; for, as may be seen by a reference to my table, cows' milk and cream do not contain more casein than sugar. The usual estimates rate the casein too high, at the expense of the sugar. This being the case, and Biedert reckoning the composition of his cream mixture from this incorrect standard, and not from any analysis either of the cream or the mixture itself, as should have been done, places his fat amount too low, as only a very poor cream is so weak in fat as his standard rates it. A mixture made as he directs is far weaker in sugar than human milk, and therefore, although, perhaps, proper for temporary use in cases of indigestion, cannot be accepted as a standard of what an infant food should be; and it entirely fails to accomplish what he says should be done—make up to the infant by an excess of carbo-hydrates the lack of albuminates which exists in the food—for it only contains about half as much sugar as exists in human milk.

All these facts show that the tendency has been constantly toward the truth, and that physicians have been learning empirically for what reasons cows' milk has failed as an infant food, and how the difficulties which its use entailed were to be overcome. The use of cream has been advised; cream and whey; diluted milk; diluted milk with milk-sugar; cream, milk, lime-water and

arrowroot-water; and finally comes Biedert's cream mixture, and he arrives more nearly at the true solution of the difficulty than any of the others, but still falls wide of the mark, from want of a precise knowledge of the composition of human milk, and of cows' milk and cream.

Investigators have thus, year by year, and step by step, been approaching the desired goal, and it needed but a touch for light to be let in upon the whole subject. Many hours and much careful and patient labor have been expended in investigations in this field, and no single worker could have done his part without having the results of the labors of his predecessors before him, to guide him a long way in the field, and give him easily the knowledge which would enable him, after much toil and trouble, to advance one little step more towards what was previously unknown. Thus, no individual investigator, no matter how important the advance in knowledge he may have made, should assume too large a share of credit; for it can be but a very small part of the great whole, and would be valueless but for the rest, into which it fits, and completes that which would otherwise be useless.

The necessary data being now at hand, it is comparatively easy to construct a food which shall, at least, be more nearly what is needed than any previous one. In making such a food, there are two matters to be considered: the proximate constituents must be in the same relative proportions

as they are found in human milk, and they must be in a medium which shall be, as human milk is, alkaline. This latter end is easily accomplished by the use of a due amount of lime-water, and is justified by the fact that it is a matter of experience, almost universally acknowledged as true, that it is a most useful adjunct, rendering cows' milk more easy of digestion by the human stomach. The quantity of lime-water to be used should be one-fourth of the total by measure. This may seem to many persons an excessive quantity; but when it is understood that if made as ordinarily directed, by agitating water with lime and then filtering, it contains only two decigrammes of lime in each litre, it becomes plain that the use of lime-water means the administration of a great deal of water and very little solid matter. The above estimate was arrived at by direct experiment; 10 cc. of freshly made, filtered lime-water, being evaporated, was found to yield two milligrammes of lime. This is a very large estimate of the amount of lime soluble in water, as may be seen by reference to the United States Dispensatory, or the National Dispensatory, both giving it as much less. That the use of lime-water (alkali) in an infant food makes a difference in its behavior with some reagents is shown by the following experiments. A food was made in the proportions which will presently be given, and 10 cc. of it agitated with ether and alcohol, as directed in my previous paper read before the Society, for the extraction of the fat; it was found that the coagulation took place in the form of a fine network, which remained permanently distributed through the lower stratum of the liquid, no sediment forming at the bottom. When an exactly similar mixture was made, except that the lime-water was replaced with water, leaving the fluid acid, and this agitated with ether and alcohol, thick, heavy curds formed, which at once sank to the bottom. Again, when two mixtures—one with and the other without lime-water—were treated with ten drops of acetic acid, the one without lime-water showed much larger, heavier coagula than that which contained lime-water. These experiments show with certainty that the addition of lime-water does alter the coagulability of the casein when experimented with, whatever may take place in the stomach; and I have already quoted Lehman's opinion that the acidity or alkalinity of milk makes a difference in the formation of the coagulum. Whatever may be the value of these artificial experiments, the great reason for the use of lime-water is that the experience of man has found it good, and that is

sufficient reason for its use in the present state of knowledge. It is quite possible that in the future something better may be found—phosphate of lime perhaps, for it is the salt which exists in milk in larger quantity than any other; but further and exhaustive study of the inorganic constituents of both human and cows' milk will be required to place this matter upon an exact scientific basis. It is very desirable that further study of the salts of milk should be prosecuted, and it is much to be hoped that in the near future exhaustive analyses will be made. The amount of inorganic matter in cows' milk is so much greater than that in human milk that, as there is at present no means of removing it without altering or destroying the other component parts, no infant food can be made exactly like human milk in respect to the amount of salts contained.

So far as bringing the other proximate constituents to like proportions with those in human milk, the first step must be to so dilute with water as to get the desired quantity of casein; the fat and sugar can be increased by the use of the necessary quantities of cream and commercial milk-sugar. Taking the averages of cream and good city milk as already given (see table), it will be found by calculation that if there be mixed together 10 cc. of cream, 5 cc. of milk, 10 cc. of lime-water, and 15 cc. of water, with 2.2 grammes of milk-sugar, the desired mixture is had. That this is the case should not be trusted to mere calculation, but an analysis of the mixture should be made, both to verify the calculation and to observe how the mixture behaves when subjected to the analytic processes, whether it in its reactions more closely resembles cows' milk, with which it is made, or human milk. The table shows the results obtained by such analyses.

The easiest way to prepare and use the food is as follows: There must be obtained from a reliable druggist packages of pure milk-sugar containing seventeen and three-quarters drachms each. The contents of one package is to be dissolved in a pint of hot water, and it is best to have a bottle which will contain just one pint, as there is then no need for further measuring. The contents of one of the sugar packages is put into the bottle, and when filled with hot water the sugar soon dissolves, and it is ready for use. The dry sugar keeps indefinitely, but after it is once dissolved it sours if kept more than a day or two in warm weather; it is understood, therefore, that the sugar-water must be kept in a cool place, and if it should at any time become sour, as is easily discovered if it is smelled and tasted, it should be

thrown out, and after the bottle has been carefully washed with boiling water, the contents of a fresh package dissolved. A milkman must be found who will serve every day fresh, good milk and cream. By good milk is meant ordinary milk, such as is easily procured in most cities, and not rich Jersey milk; and in the same way the cream should be such as is ordinarily used in tea and coffee, and not the very rich cream of fancy cattle. The reason that ordinary milk and cream are recommended, is because they are within the reach of almost every one, and not because they are any better than the rich milk of high-bred stock. If Jersey milk was to be used, it would be necessary to analyze specimens, and then make the necessary calculations as to how to dilute it to obtain the desired relative proportions of the proximate principles. When the child is to be fed, the nurse should mix together two tablespoonfuls of cream, one of milk, two of lime-water, and three of the sugar-water, and then as soon as the mixture has been warmed it may be poured into the bottle, and the food is ready for use. If the infant is healthy this quantity will not satisfy it after the first few weeks, and then double the quantity must be prepared for each feeding. Twice as many tablespoonfuls of each of the ingredients must be mixed together, making sixteen tablespoonfuls (about half a pint) in all.

This food should not be given any stronger until the child is eight or nine months old at least, but if the infant is a healthy one, it may take as much of it as it wants, but always of the same strength. A robust infant will often take three pints, or even more, in each twenty-four hours. It is an easy matter for any one to learn how to make the lime-water; and it is advisable to have it made at home, for a great deal is used, and if it is made at home much trouble and expense are saved.

With regard to the propriety of increasing, from week to week, the strength of any artificial food given to infants, there has been some question. Most authorities have advised that the foods should be increased in concentration until finally the infant is given pure cows' milk. The propriety of this procedure, during the earlier months of life at any rate, is very doubtful. Although there is some reason to believe that the quantity of solid ingredients in human milk increases from month to month as lactation goes on, such an opinion should be accepted only with great caution, for it seems likely that if there is any increase in the concentration of the milk after the colostrum has once disappeared, and the nursing

process has settled down into its even course, the increase is so slight that it may be disregarded. Analyses show that the milk of a woman whose child is two months old does not differ materially from that of one whose child is twelve or fifteen months old. If, then, nature has made no difference, which our means of analysis will detect, between the milk of a woman who has been nursing two months, and one who has nursed twelve, an artificial food which has been found to suit an infant of two months, should be made more concentrated only very gradually, and with careful observation of the effect upon the health of the infant. It is best, therefore, if the infant thrives and grows as it should, not to make any change in the food until after six to nine months of age have been attained.

With regard to the use of condensed milk as a food for young infants, I can only repeat what I said in my former paper, that I cannot believe that any article which has been canned, and kept for weeks or months, or perhaps still longer, can be so good as the same thing when fresh. My table of analyses shows the composition of the dilution of condensed milk commonly used in this city, and it shows that the proportion of fat is much too small, and for this reason, partly at least, it fails as a food. Its success is due to the fact that it contains nearly the same proportions of casein and sugar as exist in human milk. Dr. Ellwood Wilson is in the habit of directing that after the first few weeks a small proportion of fresh cream be added to the condensed milk, and this would render it still more nearly what is needed; this practice, which cannot be too much commended, if condensed milk is used, is not, however, at all a common one. Withal, I am unable to believe that condensed can be as good as fresh milk, if properly used. There are many other points of great interest, connected with this subject, which I should have liked to bring to your attention, but my paper has been already much too long.

CHRONIC NASAL CATARRH IN CHILDREN.*

BY HARRISON ALLEN, M. D.,

Professor of Physiology in the University of Pennsylvania.

In many instances the clinical history of a case of chronic nasal catarrh in the adult embraces groups of symptoms which belong to the period of childhood. Comparisons of numbers of such histories force the observer to the conclusion that the

* Read before the College of Physicians of Philadelphia.

juvenile phase of the disease includes various conditions of the nasal chambers and of the pharynx. A lady, aged thirty, reporting for the treatment of a catarrh which had persisted from the seventh year, recalled the distress at that time experienced from frequent passage of mucus from the naso-pharynx to the oro-pharynx. A young man, aged twenty, who suffered from obstruction of the nasal chambers, and whose tonsils were normal at the time of examination, remembered the fact that these bodies were of large size when he was quite young. A third patient, aged thirty-five, suffering from copious muco-purulent discharge from the nose, complicated with pharyngitis, was confident that the habit of hacking had annoyed him as early as his ninth year to as great a degree as at the date of reporting for relief. While it must be conceded that in recording the clinical history of an adult, allowance must be made for lapses of memory and for the probable co-existence of exanthematous and of diphtheritic sore-throats, it is certain that some of the little patients who come under care exhibit symptoms which are apt to persist in some modified form in adult life.

In the light of such evidence it becomes a matter of interest to ascertain what peculiarities, if any, are to be found, which characterize chronic nasal catarrh in children.

Accepting as an axiom that this disease cannot be appropriately studied without a correct understanding of the structures of the nasal chambers, it must follow that the differences between the adult and other juvenile phases of the disease may be expressed in some degree by the differences between the peculiarities of the chambers themselves at the two periods.

In the child the vestibule is small, the floor is raised, the inferior meatus is shallow, the mucous membrane is of a delicate red color, and the eminences corresponding to the anterior ends of the inferior turbinated bones are rounded, and relatively of greater length than in the adult.

In part owing to the difficulties, and in part to inherent distinctions, the juvenile aspect of the disease is marked by a number of negative features. Thus, the membranes are never infiltrated with the products of inflammation, or corrugated, or ulcerated. The lower border of the inferior turbinated bone is never concealed within a deep inferior meatus. The septum is never, or almost never, deflected, unless a history of injury explains such deflection. Disease is never located above the respiratory tract. Atrophic catarrh is unknown.

Symptomatology and Diagnosis.—Congestion and acute inflammation of the nasal mucous membrane is common in childhood. The discharge in the beginning of the attack is almost always mucoid. The serous stage so commonly present after profound impression in adults, is not recognizable, and the transition is usually abrupt from a discharge of mucus to one of muco-pus. If air passes freely through the chambers the discharge is apt to dry and to form "crusts" or "scabs." These collect for the most part in the vestibule, though they may form at any portion of the respiratory tract. The discharge will often remain muco-purulent throughout the entire treatment, so that instead of expecting a return of the mucoid stage the practitioner should look forward to a gradual cessation of the amount of the discharge. The muco-pus in favorable cases becomes thicker as the case improves, and toward the close is often of the consistence of curd.

The child either "sniffles" in order to draw into the nose the discharge which, from the shallowness of the vestibule, inclines to flow outward from the nostrils, or it exhales or "hawks" if it inclines to fall into the pharynx. By careful observation of these acts, it can be ascertained that the place at which the discharge is most annoying (all things remaining the same), is also the place at which the greatest amount of obstruction exists.

Should the tonsils be very large and establish mouth-breathing, care should be taken not to confound the tumid state of the membranes of the nasal chamber with the evidences of local disease. Although the two conditions of nasal catarrh and enlargement of the tonsils often exist together, they need not.

When tumid tonsils are present, the probabilities are in favor of the adenoid growths at the roof of the pharynx being in the same condition. The naso-pharynx in such patients is occupied with tenacious mucoid discharge. The nasal chambers and the naso-pharynx, considered as parts of a single chamber, are shut off from communication with the oro-pharynx and the normal downward flow of mucus prevented. The mucus can be at times brought away through the nose by the handkerchief, and the impression may be erroneously received that the discharge, instead of being pharyngeal and mechanically retained, is catarrhal, and that it originates in the nose.

It need be scarcely necessary to say that the presence of mucus in a naso-pharynx which is thus narrowed, renders the danger to aural complication decided; and, while the condition is one not ad-

mitting of classification with cases of true nasal catarrh, the diseases of the nose and ear are inextricably associated.

The general health is rarely good, and symptoms which relate to mal-nutrition are so pronounced that they have received careful attention at the hands of the writers on the diseases of children. This subject is elaborated in the succeeding paragraphs.

Etiology.—Chronic catarrhal states in childhood are invariably associated with other effects of mal-nutrition. While this is not a novel statement, it is at least one which has been imperfectly formulated. Such effects should not be dismissed as being simply those of scrofula and of rickets, but should be exactly referred, as far as it is possible so to do, to the laws of development. Many conditions are present in patients who suffer from catarrh, which may be called errors in development. It is true, these errors are not of the kind denominated "variation," or "anomaly," but are pathological, and may be regarded as the results of precocity or retardation occurring in rapidly-growing tissue. They are conspicuous in bone-tissues, tooth-tissues, skin-tissues, lymphatic tissues, and in nerve-tissues.

From the earliest period in development to its completion at the twenty-first year, disease will modify structural processes much more readily and profoundly than at any subsequent period. The tissues may be said to be more plastic during the formative period, and to retain the impress of morbid action a longer time, than in the adult, and to carry into the future the results of this impress in altered relation or proportion of the formed elements. It is not intended in this place to show that chronic nasal catarrh is in any respect peculiar in this regard, but to invite attention to the operation of such forces which appear to have escaped detection.

The period of childhood is marked by changes as great in the proportions of the parts of the head and face as in any other of the body. The growth of the brain and the development of the permanent teeth are among the more striking of these. Clinical writers lay great stress upon the influence exerted on the economy, by the errors of the cerebral and dental growths. Are the influences they exert in the etiology or in the maintenance of nasal catarrh to be ignored?

The condition of the development of the brain in connection with those of the nasal chambers, while one of great interest, presents difficulties for the investigator, since the examination of large numbers of examples would be required before

conclusions worthy of credence could be reached. Ophthalmologists have indeed noted that accelerated rates of development of the brain exist with a disposition to myopia. If such be the case, it is rational to conclude that the shapes of the nasal chambers will be in correlation with the states of the olfactory nerves, and thus the influence which exists between the brain and the eye, will be found also to exist between the brain and the nose. The extent to which chronic nasal catarrh may be found among myopes cannot be formulated.

There is no doubt that the patients are as a rule in an unnatural mental condition. The mind is either precocious or dull; the temper is irritable, and the disposition intractable; digestion is delicate, and reflex disturbances arising therefrom are of frequent occurrence. The patients belong to the class of subjects that develop morbid appetites, and, in girls, yield the predisposing causes which create so much disturbance at the approach of puberty. Chorea is occasionally noticed as a complication. In one example, a child of precocious intelligence, of delicate constitution, and who had nearly perished during an attack of acute pleurisy, the habit of exhaling air from the nostril was acquired after all symptoms of catarrh had ceased.

From the fact that with chronic nasal catarrh, errors of development of the teeth and rates of growth and nutrition of the nails are often associated, it is convenient to examine the relations between the nails, the teeth, and other structures. By way of introduction to this topic, it can be said that in pathology the connections between the hair, the nails, and the teeth are numerous.* Abnor-

*From the fact that the writer's biological and clinical studies have been pursued conjointly, he trusts that it may be thought admissible to introduce at this place some reflections concerning the nails and the teeth. These structures are of co-relative value in mammals generally. Blunt, flat teeth are always associated with hooved digits, and sharp, conical teeth with clawed digits. Adopting the methods of the evolutionists, it may be assumed that the same forces which have been operative in changing the forms of teeth are also operative in changing the forms of the hoofs and claws. This co-relation is not found in the earliest of the mammalia. In the process of evolution of the quadrupeds as they exist about us from the few generalized types known to have flourished in the past, it can be inferred that the impress upon the nutritive processes which would effect the forms of the teeth would also impress the entire tegumental series of the organism; not only the teeth and nails would be in common affected by common causes, but the hair as well. Confining these remarks, however, to the nails and teeth, it is probable that the changes of food-supply, necessitating corresponding changes in habit, would most probably effect the claws and hoofs sooner than the teeth, since the

mal development of the teeth occurs in congenital hypertrichosis. Hair and teeth are commonly found in dermoid cysts. In man and in ruminants, hairy warts are found upon the cornea. In congenital syphilis, the cornea, the teeth, and the nails are all liable to peculiar inflammatory invasions. Is it not more than a surmise that since all these structures—the hair, nails, enamel-organs, and cornea—arise from the *epiblast*, and are strictly tegumental in nature, that they may be found affected together? Be this as it may, the nails and teeth are certainly to be considered together in studying chronic nasal catarrh in children, the nails at all times, and the teeth during the formative period of the enamel-organs.*

I have recently examined 96 children, with the object in view of determining to what degree a connection could be traced between the teeth and the nails in individuals, many of whom, if not all, were known to have been subjected to neglect and to the various inherited effects which could reasonably be accepted as tending to retard development.

Of the entire 96, 15 children had white spots on the finger-nails in abundance; 5 of these had decided defective dental development—that is to say, excessively chalky enamel—distorted and disfigured crowns, etc.; 3 had moderately chalky crowns, but no distortion; 7 had no appreciable defect.

No defective teeth were found in the remaining 81 children, so that the existence of dental defect exactly correlated with the spotted finger-nails. Of the 15 children thus selected, a little less than half the entire number had spotted nails but no dental defect. No attempt was made to ascertain any defect of rate of eruption, for the data obtained from the inmates of an asylum for destitute children would be unreliable. It is quite likely that the numbers of defects of teeth would be increased rather than diminished by more careful examinations made by dentists or other persons accustomed to detect minute abnormalities. Concerning the defective teeth and nails, it is conceded that they may have arisen from acute ill-

ness, as in the exanthemata, or from gingival inflammation, as in congenital syphilis. The "measles-tooth" was found but in a single individual, whose case was not enumerated. For the rest, it is quite possible some of the appearances may have been due to syphilis, though the pegged tooth was found in a single instance only. No account was taken of the occurrence of catarrh in the inmates, for although it is probable the condition existed, it was not reported as present by the attendants. The disease is rarely recognized among the children of the poor, where the symptoms are not likely to receive attention.

From a careful study of nine patients from the writer's practice, it was found that five exhibited white spots on the nails of the hand, and defects in the form and irregularity of rates of eruption of the teeth. In a young lady, aged fifteen, who came under care for this phase of catarrh, the superior lateral incisors had never been erupted, while the left deciduous superior canine tooth had remained in the arch. In a second case of a girl fifteen years of age, who had been much neglected, the depression remaining upon the vertex (answering to the anterior fontanelle), was conspicuous, the teeth were irregular, the vault of the hard palate high and narrow, the disposition shrinking and irritable, and the mental faculties dull. In such patients, the epiphyses of the bones will be seen to be too large for the shafts, particularly in the case of the radius as it enters into the composition of the wrist-joint. At the same time, the finger-nails are often marked by large white spots, and the teeth, with milky opacities of the enamel.

The bones being slow in growth, the function of manufacture of blood-corpuscles is largely withheld from the medulla, and retained for a longer period than is natural in the blood-vessel-glands, notably the thyroid body, the tonsils, and the lymphatic glands. Hence a disposition exists for these structures to undergo hypertrophy. If this method of reasoning be accepted, it is evident that the presence of enlarged tonsils need not be regarded as a primary cause of the condition above outlined, though doubtless they may aid in a secondary manner in maintaining morbid determination of blood about the head; and if they are sufficiently bulky to cause obstruction in respiration while the mouth is closed, will in themselves create a class of disturbances peculiarly their own. All that is to be emphasized in this connection is the fact that the causes of tonsil enlargement are due to nutritive conditions.

(To be continued.)

latter are more resisting, and at least in many genera are completely formed while the claws and hoofs are of continuous growth, and would be more readily influenced by changes in the surroundings.

*Among the applications of the rate of the growth of nails in connection with diseased states, reference may be made to papers by Dr. S. Weir Mitchell in paralysis, Dr. J. M. DaCosta in typhoid fever, C. E. Hasse in cyanosis, and Poland and Langenbeck in aneurism.

RIGIDITY OF THE CERVIX UTERI AND THE USE OF ERGOT.

BY S. W. DICKINSON, M. D.,
Of Marion, Va.

I have been hoping some one would follow up the article of Dr. Boardman Reed in *REPORTER* (January 6, 1883, p. 6), on "Methods of Overcoming Rigidity of the Os Uteri—How not to Use Ergot," with additional suggestions. Such cases (*REPORTER*, December 16, 1882, p. 697) as called out his paper, and the rather caustic review of our friend, Dr. Hiram Corson, in *Pittsburg Medical Journal* for August, 1883, but too frequently come to our ears, and besides rigidity of the cervix is "one of the chief causes of delay in the first stage of labor," and causes a great amount of preventable suffering, not to speak of lacerations of cervix and consequent troubles.

Ergot cannot overcome rigidity of cervix caused by premature discharge of liquor amnii, or as seen in either nervous or plethoric women. Headland (*Action of Medicines*, p. 261) tells us that ergot "is a stimulant to the muscular nerves of the uterus," and we know that by it is produced contraction of the uterine muscular fibres. Ergot then produces just the opposite effect from relaxation, and it is as sensible to try to lift one's self over a fence by his boot-straps as to give ergot to overcome a rigid cervix. So then, as both Headland and Playfair teach, we would not give ergot unless the os was dilated or dilatable, and there was no obstruction to a speedy delivery; for if "not followed by a rapid delivery a condition is produced which is serious to the mother," and "extremely perilous to the child" (Playfair). Chloroform the great relaxant of muscular contraction, "tends in a marked degree to diminish uterine action," and according to Playfair (p. 289), is "practically speaking, generally not admissible until the head is in the pelvic cavity." Dr. Reed prefers morphia and atropia hypodermically, but mentions chloral. Opiates by the mouth or enema were given by Cazeaux, when bleeding, hot baths, etc., failed, and remembering the power opium has to relieve spasm of the intestines in colic, etc., I would not hesitate to use it when other agents were rejected by the stomach.

Probably in this State (Virginia) the fluid extract, or tincture of gelsemium, first recommended by Dr. Payne, of Lynchburg, is as largely used as any other agent, and this, with chloral, is a capital combination in many cases. But in cases of a highly nervous and emotional tempera-

ment, rendering the patient acutely sensitive to her suffering, I am prepared to say with Playfair (p. 289), "I know of nothing which answers so well" as chloral, "and I believe its administration to be far more effective under such circumstances than any of the remedies usually employed." The following case will illustrate this: Some eight years ago I saw a lady in consultation, and found her tossing about in bed, pulse over 100, and apparently becoming exhausted. The physician in attendance, disheartened by long waiting, thought the forceps the only chance. I found the head had not escaped from the os, owing to a rigid cervix, and gave twenty grains of chloral, and repeated it in less than half an hour. Our patient became quiet; slept between pains, pulse came down, and she was delivered in a few hours with no other aid than helping rotation a little with my fingers.

Patience and a cheerful demeanor, though mentioned last, are by no means the least important factors in the management of these cases, and he who can command these virtues will succeed in cases where a nervous and fearful man will fail. In conclusion, while I would disclaim originality for the above views, still I hope they will interest some one, and be of service to those who cannot yet call on a past experience to help them in times of trouble.

REPORT OF A CASE OF TRISMUS NASCENTIUM.

BY N. B. KENNEDY, M. D.,
Of Hillsboro, Texas.

About two months ago, Mr. Ward, section boss of the section below Abbot Station, on the M. P. R. R., sent me a telegram to come at once to see his infant child.

On arrival, found a plump, hearty baby seven days old.

The mother gave me the following history: When the child was two days old, she (the child) had a very hard convulsion, and the convulsions had been coming on every hour since without intermission. Several physicians had been called, but were unable to diagnose the case.

An examination being made, I found the following conditions: The umbilicus was very much inflamed, and attached to one edge of it was a fungous growth some two inches in length and as large as the large end of a goose-quill, and somewhat resembling the vermiform appendix of the cæcum.

I recognized a case of trismus nascentium by the following symptoms: Rigidity and stiffness of the muscles of the lower jaw, neck, and abdomen—*risus sardonius*—spasm, ushered in by *opisthotonos*—protrusion of the tongue—rapid pulse and cold sweat. The fungous growth was inflamed, and pressure upon it was sufficient to excite the spasms. Deciding, therefore, that the fungous growth was creating all the disturbance I resolved to remove it. I caught it in my forceps, and with a sharp pair of scissors cut it off smooth with the surface of the umbilicus, restraining all hemorrhage by the free use of carbolic acid applied to the bleeding surface. I placed the infant on the following treatment:

R. Potassii iodidi,	
Potassii bromidi,	āā ʒj.
Potassii carbonatis,	ʒij.
Ammonii bromidi,	ʒss.
Infus. columbæ,	ʒvi.

M. Signa.—Five drops every three hours in mother's milk.

R. Iodoformi,	ʒj.
Acidi carbolici,	gr. x.
Ung. petrolei,	ʒj.

M. Make an ointment. Sig.—spread on a soft cloth and keep constantly applied.

I ordered a tepid bath every morning for the babe; and instructed the mother to draw the milk from the breast, and give it, as the babe was unable to nurse.

Two days afterwards I received a second telegram summoning me the second time.

On arrival, the mother informed me the babe was still having convulsions, but that they were much lighter in character and at longer intervals. I found the stiffness of the muscles of the lower jaw, neck, and abdomen had greatly improved. So much so the babe could now take the breast, and nursed heartily. I ordered the dose of the medicine increased, and the baby had only three or four convulsions more. The convalescence was rapid and marked. There was no fever throughout the attack; and the baby continued to grow, and at this writing is the pride and delight of her parents.

In conclusion, permit me to say, I have never read of a similar case in any of the text-books, and during an active practice of twenty-five years have never met with such a case before.

If any of your numerous and intelligent readers have ever had such a case, I would be glad to hear from them.

And I would like further to know if I did right in removing the fungous growth in the manner I did.

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL.

BY CHARLES K. MILLS, M. D.,

Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic; Neurologist to the Hospital.

Reported by WILLIAM H. MORRISON, M. D.

Organic Hemianæsthesia; Methods of Studying Sensory Disturbance; Differential Diagnosis of Organic from Hysterical Hemianæsthesia.

GENTLEMEN: I propose this morning to lecture to you on true-organic hemianæsthesia, and the differential diagnosis between this affection and hysterical hemianæsthesia. The different methods of studying sensibility clinically will be described and discussed.

This patient, Annie H., age 40 years, single, white, has been in the nervous wards of this hospital since 1877. She came to this country from Ireland in 1860. As far as she knows, her family was healthy. She herself never had rheumatism. When I first saw her, she was suffering from an apoplectic seizure, in which she remained profoundly unconscious for several days, and did not regain her intelligence entirely for two or three weeks. On coming out of this condition, found that she was paralyzed on one side of the body, and not only was motor paralysis present, but there was also complete loss of sensation on the same side.

This attack appears to have been the third one that she had. During the continuance of the unconsciousness, there were marked variations of the pulse, respiration, and temperature. Touching the dorsum or sole of the foot produced reflex movements, which were more marked on the left than on the right side. For some time after the apoplectic attack, she suffered from headache, which was most marked over the anterior half of the left side of the head. This pain was increased by percussing any part of the cranium. She also had pains in the paralyzed shoulder. During the past few years her mental and physical condition has remained about the same, with the exception perhaps that the muscles and nerves have undergone further degeneration.

Let us now study her present condition. As you see, she appears to be pretty well preserved for a woman who has been sick so long. The face exhibits but little deformity. If any thing, there is a little smoothing of the lines of the face on the left side; but she can close her eyes firmly, corrugate the forehead equally, and draw up the corners of the mouth to the same extent on the two sides. She can slightly move the left arm, but cannot lift it. The arm is not much wasted. Contracture is seen at the elbow, wrist, and fingers, which is most marked at the wrist. It is, however, readily overcome with a little force. She is able to lift the left leg with about the same facility as she lifts the left arm. The right limb is also crippled, but from an entirely different reason. On this side there is ankylosis of the knee, with disease of the bone. There is contracture at the ankle of the left side, the foot being

thrown into a condition of *pes equinus varus*. When this condition affects both sides, it has a certain diagnostic value, to which I shall allude farther on.

The examination of sensibility or sensitivity is the next point to which I will call attention. The object of this lecture is not simply to make a diagnosis of this case, but also to teach you some of the practical methods of studying the sensibility. You are familiar with the mode of examining for loss of motion, by the power to make various voluntary movements, by electricity, and by other methods. But the clinical study of sensation is too much neglected by practitioners. Although so much attention has been paid to the localization of brain lesions, yet comparatively few of the cases of disturbance of sensation due to cerebral lesion have been placed on record. This is particularly true with reference to disorder of special sensation. The reason of this is that disturbance of sensation is readily overlooked by a careless investigator, or that he does not understand the best method of examination.

An interesting study among yourselves would be as to the normal differences of sensitivity. A work entitled "Inquiries into Human Faculty," has been recently published by Francis Galton, in which some of the results of experiments in regards to sensitivity of individuals in ordinary health are given. He has shown that the powers of discrimination are much finer in some than in others, and that the power to detect small variations is greatest in the intellectually ablest. He has also determined, contrary to what we should have expected, that sensitivity is higher in men than in women, basing his opinion on the fact that as a rule men are employed as tuners of piano-fortes, tasters of wine, and sorters of wool, and in other occupations requiring delicacy of touch, taste, or of other senses. This same author has also made some curious observations in regard to such senses as sight and hearing.

In disease, involving disorder of sensation, you should study sensation as regards pain, touch, temperature and weight. You should investigate then the special senses. The sight should be studied in reference to the near and far points, the ability to discriminate colors, the fine points in pictures, and so on. In reference to the ear, not only should it be determined whether or not the patient hears, or hears better with one ear than the other, but also as to his power of determining low and high notes.

The ability to detect painful impressions can be determined in various ways. I have here an aesthesiometer with two sets of points, one pair being blunt and the other sharp, and so arranged that either or both pairs may be used. First applying the blunt points to the right side of the face, she feels them distinctly; but on the left side, although I press forcibly, she feels nothing. As I pass across the forehead she detects nothing until I get to the right of the median line, and then she feels the points. The same is true of the chest. There is complete analgesia and anæsthesia to the left of the median line. The left leg is in the same condition. I now try the sharp points and obtain the same results. I could make a pin-cushion of the left side of her face without her feeling it. The moment I cross the median line,

and not before, does she feel the presence of the needles. So much for the determination of cutaneous sensibility both for pain and touch.

Her power to discriminate between different temperatures is also lost. I have seen two cases, and they are the only ones which I can now recall, in which the sense of temperature was lost, while the sense of touch still remained. In testing this point, I shall use two sponges, one dipped in ice water, and the other into very hot water. On the right side she readily tells which sponge is placed on the arm, but on the left side she feels neither the hot nor the cold.

The experiments should be continued still further. You should examine the parts below the skin and test for muscular sensitivity and the sense of weight to pressure. An instrument has been invented for this purpose, called a piesmeter. This instrument consists of a cylinder about three-fourths of an inch in diameter and three inches long, in which is a piston which is kept pressed back to its fullest extent by a spring. At the end of the piston-rod is a flat disc, which is placed against the skin. The operator then presses against the end of the cylinder, thus forcing the piston into the barrel, and the amount of force exerted is readily read off on a scale on the instrument. On the right side she feels even the weight of the instrument, but on the left side, the strongest pressure elicits no response. Galton, in his experiments on this point, employed a series of test weights, consisting of a number of common gun-cartridge cases filled with alternate layers of shot, wool and wadding, and closed in the usual way. The appearance of these is identical, and their weights form a geometric series. The testing is performed by handing to the person operated upon, pairs of weights until his power of discrimination is approximately made out, and then proceeding more carefully. In a case as marked as this, the coarsest methods will suffice. I have here a series of ordinary weights from a few ounces to four pounds, and you see that the heaviest weight is not felt when placed upon the left arm.

The special senses next call for investigation. The eyes have been carefully examined with the ophthalmoscope and by other methods, and although the power of the left eye is less than the right, and the ability to perceive quickly is diminished, yet there are no changes in the retina or optic nerve.

The acuteness of the hearing can be determined roughly by the watch. But if it is desired to determine the ability to hear notes of different pitch, a whistle something like that used by Galton should be employed. He made a whistle which consisted of a piece of brass tubing, whose internal diameter was less than one-tenth of an inch. Into the lower end of this tube a plug was fitted which could be drawn out or pushed in at will, thereby enabling the operator to vary the length of the tube as desired. When the plug is drawn out the note is low; when pushed in, the note is high. On testing persons of different ages, he found that as age advanced, the ability to hear high notes diminished. He also experimented on animals in the Zoölogical Garden, and found that animals of the cat species had the greatest power in hearing high notes. Small dogs can hear much higher notes than can large dogs.

I have carefully examined the sense of taste, and have not found any marked impairment of either side.

One of the most difficult things to test is the sense of smell. Pungent substances, such as ammonia, should not be used. What is needed is something that has a dead smell without any pungency. Bi-sulphide of carbon would probably answer well, if there were not certain objections to its use. We shall try her to-day with rose-water. When the bottle is held to the left nostril she smells nothing, but on the right side she recognizes it immediately.

(To be Continued.)

NEW YORK HOSPITAL. -

CLINIC OF PROF. WILLIAM H. DRAPER.

Reported by W. H. SEELYE, A. M., M. D.

Scabies.

The history of the next case is as follows: The patient, J. S., is 17 years of age, single, born in Prussia, and is a sailor by trade. He always enjoyed good health until two and a half years ago, when by overstraining himself he induced a left inguinal hernia. He did not have any eruptive diseases in childhood, and he has never had syphilis or gonorrhoea. He has not been in the habit of drinking to excess. Two weeks ago he noticed an itching between the fingers of his left hand, and this was followed by an eruption of a papular and vesicular character, which quickly spread to the other hand, and to the wrists, and to the arms, and the inner side of the elbows, and then to the chest, genitals, and thighs. The vesicles discharged a thick fluid, which dried upon them and formed crusts and thick scabs. This was most marked on the inner surfaces of the fingers, and at their junction with the hand. He says he does not know how he became infected.

You will observe, gentlemen, that although this eruption is pretty general in its distribution, yet it is mostly confined to those parts of the body which are within easy reach of the patient's hands, where, you remember, it started. So you find very little eruption below the knees, but there are some vesicles on the thighs, and they are very distinct upon the foreskin of the penis, and well marked upon the arms, and especially so upon the hands and wrists. But you will notice that there are none upon the face and neck. If you will examine him more carefully, you will observe that there is no distinct, peculiar, or individual character to the lesion; but there are some erythematous spots, and some vesicles, pustules, blebs, and superficial ulcers, and some small papules, the summits of which have been torn off by the finger nails in scratching, and they are therefore now surmounted by a little drop of dried blood. This man is a museum, so to speak, of all the various forms of cutaneous lesions. He has in fact a polymorphous lesion.

The disease from which he is suffering is scabies. And this polymorphism in the eruption is very characteristic of scabies, after it has existed for some time. This man dates the beginning of his trouble back to only a fortnight since, and so the disease has made very rapid progress. You will

not very often meet with this disease in private practice, but you will see it every now and then, and you will find it a most satisfactory disease to treat, after you have succeeded in forming a correct diagnosis. It depends upon the presence of a parasitic animal, and generally in man, of that particular variety called the *acarus scabiei*. It is contagious, as are all parasitic diseases. But the degree of this contagiousness depends to a certain extent upon peculiarities in the individual exposed. All persons are not equally sensitive to the attacks of this parasite. And this fact is also true as regards the susceptibility of different individuals to those minute organisms called bacteria, which are supposed, by entering into the blood, to cause that class of contagious diseases of which diphtheria is an example.

In either case something besides the contagious element is necessary, and that is a proper host. These integumentary parasites are careful to select their host, and they will often decline to live upon certain bodies, because they do not find them congenial. And I suppose, gentlemen, that a certain number of you might hold this man's hand for a time, and not take the itch from him. But it is probable that a large proportion of you would. There are many curious features in the natural history of this disease which it would be interesting to talk about; but as our time is limited, and as they are not essential to an understanding of the disease, I will not stop to discuss them now.

But this much it is important that you should know, namely, that this *acarus* is an insect which can readily be seen by the naked eye, and that while it thrives upon the integument generally, yet it chooses for its invasions certain special parts of the body in preference to others. Thus the tender integument upon the inside of the fingers, and the wrists, the axillae, the genital organs, the toes, and the parts around the ankles, are the principal seats of election. And in certain trades-people, and artisans, they sometimes select other parts by preference, to which they are attracted by reason of the unusual warmth or pressure to which these parts are exposed. Thus in tailors and shoemakers, and those who ride much in the saddle, and in those who retain the sitting posture constantly while at their business, it selects the skin of the buttocks just over the tuberosities of the ischia.* The disease most frequently begins in the hands, and it is transferred by them to the other parts of the body which are handled the most.

The insect bores its way into the epidermis, and does not live upon the surface of the skin. It is, therefore, really not an epizoon, though it is classed among them. The female makes her nest between the horny and the mucous layers of the skin, and there she lays her eggs, and in a week or ten days they become matured and the young are discharged from the ova. The male also burrows, but not so deeply, but it migrates farther.

Symptoms.—The first subjective symptom of this disease is usually an itching between the fingers, which is sometimes extremely severe. And in nervous individuals, after the disease has spread to other parts, there is a general hyperæsthesia of the skin, and they scratch themselves everywhere they can reach. So only a small portion of this polymorphous eruption which you see is produced

by the insect, but it is largely due to the violent scratching and tearing of the skin by the patient's finger-nails. Thus a general eczema may be produced as a consequence of this constant irritation.

The next objective symptom is the appearance of an eruption, which is somewhat peculiar in its early stages. Little vesicles first appear between the fingers, and upon close examination a canaliculus may be seen running from each of these. Each of these canaliculi is made by the burrowing of an insect just beneath the epidermis; and each is a quarter of an inch or more in length, and terminates in a vesicle in which the insect has made its nest and laid its eggs.

This little canal has been said to be the essential diagnostic element of this disease, and if you do not find this, the suspected vesicle is not due to scabies. But I think this is too strong a statement, for you will now and then find vesicles which contain no animal, and hence there is no canal leading to them. There is no difficulty, as a rule, in finding the acarus. Simply take a common sewing needle and insert it into the canaliculus and carry it along until it reaches into the vesicle, then rupture the vesicle and bring the needle out, and upon its point you will usually find the animal. But you must remember that while this is the characteristic vesicle of scabies, yet its peculiarity is often destroyed by scratching, and this is especially true as regards children. The crucial test in all cases, however, is the discovery of the insect.

The prognosis is always good in these cases, if they are properly treated.

The rational treatment, which consists in removing the cause of the trouble, is perfectly applicable here. This may be done in many ways, for there are many means of destroying the insect. Sulphur, however, is the classical remedy for this disease; and it was used in the earliest times, and is probably to this day the most universally employed for this purpose. Its action on the skin may be obtained in various ways, either by means of sulphur baths, by fumigations, or by ointments. Perhaps I can do no better than to describe to you the way the treatment is carried out on a large scale in the hospitals of Paris, and particularly in the hospital of Saint Louis, where a special department is devoted to the treatment of skin diseases. Here they have a large apartment, into which every morning the patient is sent naked. The first thing each one does is to thoroughly soap himself with soft soap, and then each soaps his neighbor over those parts which he cannot himself reach. This is done in order to soften the epidermis. The patient then goes into another apartment where there is a hot bath, into which he gets, and lies there from twenty minutes to half an hour. He then dries himself and goes into another room, in the middle of which stands a large tub filled with an ointment which consists of carbonate of potash one part, to flowers of sulphur three parts, and lard eight parts. Each patient now rubs this ointment freely into all the crevices of the skin, and then dresses himself again in his own clothing. This can be safely done, for the process is so thorough that the ointment which is left on the skin effectually destroys all the insects which may be present in the clothing. After repeating this process

from three to five times, the most obstinate cases of scabies are cured. There is no better plan of treatment than this to follow, even in private practice, for it can be carried out at the patient's home almost as conveniently as in a hospital. This process of softening the epidermis before applying the ointment is very important, in order to thoroughly destroy the vesicles, and the eggs, and the immature animals, which are concealed in them. Another important point to remember is to apply the ointment to the whole surface of the body, and not simply to the parts which seem to be affected. For this is a migratory animal, and without this precaution you may fail to destroy some which have wandered to distant parts. The head and neck are the only parts of the body which can be spared, for it is extremely rare to find that they have invaded these regions.

Carbolic acid, creasote, iodide of potassium, and the salts of mercury, have also been successfully used in this disease, for they are all destructive to the lower forms of both animal and vegetable life.

A peculiar fact in the history of scabies is that the same theories have been held with regard to the significance of the acarus, as have more recently been held by investigators with regard to those low organisms which are now supposed to enter into the circulation, and to produce the various forms of infectious fevers. That is, it has been maintained by some that the acarus is not the cause, but only one of the products of the disease. It is, they said, an example of spontaneous generation, for the fluids of the body are in just that condition which is favorable to the development of these animals within the vesicles. And so they are only an incident, and have no share in the production of the disease. On the other hand, the idea prevailed with many in the sixteenth and seventeenth centuries, that the psora was the basis not only of the itch, but of all diseases. It was for instance supposed that this animal got into the bladder, and so caused diseases of the kidneys, or by getting into the joints it caused gout; and so it was considered to be the universal cause of all maladies. The same notion prevailed for a long time in regard to those spores which cause prurigo favosa, and herpes circinatus. And the view taken by Mr. Erichsen until recently in regard to prurigo favosa, is that it is a disease of inflammatory origin in which spores are found as a complication, and not as a true cause of the disease. In like manner, many now maintain that the bacteria which are found are not the cause, but only an incident in the development of surgical fevers, diphtheria, and the like.

MEDICAL SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Discussion on Composition of Milk and Infant Feeding. (See Pp. 193 and 225.)

The President called attention to the following points for discussion:

1. Any method of analysis which is to be generally accepted must be susceptible of verification.
2. All previous analysts agree about the

amounts of water, fat, and ash; therefore, about the amounts of casein and sugar alone is there any disagreement.

3. Further, all agree about the sum of the amounts of these two elements (casein and sugar), but diverge widely about their individual amounts.

4. If it has been proved that, collectively, casein and sugar amount to about eight per cent., and that the sugar is about seven per cent., it then follows that the casein is only one per cent.

5. When subjected to the same method of analysis, human milk yields nearly seven per cent. of crystalline sugar, and cows' milk about four per cent.

6. To be able to make a proper food for infants, we must first understand the composition of their natural food—human milk.

7. Is there any great and important difference between the casein of human milk and that of cows' milk, except that it is contained in the latter in a larger proportion?

8. In preparing cows' milk for infants, clinicians usually direct that it be diluted, and some sugar and lime-water added; but more precision of advice is needed.

9. What is the best method of making an artificial food like human milk?

10. What is the propriety of increasing the nutritive quality of the food from month to month, as the child grows older?

11. What can be said of condensed milk as a diet for infants?

Dr. J. Cheston Morris, in opening the discussion at the request of the chair, said: It gives me great pleasure to pay my tribute of respect to the accuracy and industry which Dr. Meigs has so evidently exhibited in his investigations, though they have led him to very different results from my own. Accurate analysis, even of inorganic bodies, is difficult, as many of us know who have tried it; but accurate analysis of inorganic mixtures is far more so, from the changes continually going on in them.

A perfect method of milk analysis is probably not yet attained. Dr. Meigs having replied to a question from Dr. Morris that he obtained the amount of fat present by repeated washings of the milk with ether and alcohol, Dr. Morris resumed: The extraction of all the fat present is difficult, owing to the globules being surrounded by a thin membrane of casein; this has been proved by Mitscherlich, who advises the previous agitation of the milk with a small quantity of solution of caustic potash, when the ether immediately dissolves out the fat. Perhaps the best process yet devised is that of the Society of Public Analysts of Great Britain, given at length in various numbers of the *Analyst*.

The amount of water present in normal milk does not vary very much, nor does that of ash; but judging from the report of over 12,000 analyses, made by Dr. Viette for the Aylesbury Dairy Company of London, that of the fat in cows' milk does vary from 3 per cent. to between 5 and 6 per cent. Any result less than 3 per cent. is regarded as proof of adulteration. So far is the amount of water, ash and fat from being regarded as agreed upon among analysts, that the problem with them generally has been to obtain a method which

would enable them readily to ascertain this latter factor; and Mr. Hehner has constructed, as a means to detect adulteration, a table showing the relation between the specific gravity and the fat present, the solids *not* fat (*i. e.*, casein and sugar), being taken as constants. To what extent these are really so may be judged from the analyses of Dr. Viette, above quoted, showing a maximum of 10.31 per cent. and a minimum of 8.97 per cent. in over 12,000 analyses. The total average is about 9.5 per cent. in cows' milk. But all cows' milk is not alike; that from different breeds has marked peculiarities and differences, perceptible even to the eye and the taste. The milk from the Jersey cow is rich in fat, but poor in casein and sugar; that from the Durham is comparatively watery, and poor in fat and sugar, though relatively rich in casein; that of the Devon is nearly as rich in fat as that of the Jersey, and in casein as the Durham, and richer in sugar than either of them. The commercial uses of these breeds in butter and cheese making, bear out the above statements.

Another reason for thinking that 1 per cent. is too low an estimate of the amount of casein in human milk, is that such a proportion would hardly supply the needed amount of nitrogenous food to the infant. Lehmann tells us that the amount of milk secreted daily by the human female may be estimated at 2.2 per cent. of her weight; so that a woman of 150 pounds would produce 3.3 pounds milk, or 23,100 grains—rather more than a quart and a gill. If only 1 per cent. of this is casein, it would give only 231 grains; if she weighed only 120 pounds, there would be only 2.64 pounds of milk, of which only 185 grains would be nitrogenous. Authorities on diet tell us that the human being requires food amounting to one-twenty-fourth to one-twentieth of his weight, of which one-fifth, or 1 per cent. of the whole, should be nitrogenous. Applying this rule to the infant, which has certainly larger needs for food for development, a weight of 10 pounds, or 70,000 grains, would require 700 grains of nitrogenous food—a figure nearly approximating that which would be yielded by a milk containing 3 per cent. of casein. In colostrum, however, we have a fluid poor in casein, but rich in sugar and fat.

Casein and sugar, we are told by Lehmann, are both soluble to some extent in alcohol. I have studied the question of the identity of casein of cows' and human milk, without being able fully to satisfy myself, but am inclined to regard them as differing mainly in coagulability. This may depend on the salts with which they are associated, as may also the acidity or alkalinity of the milk. These salts have, relatively to the serum of the blood, a preponderance of phosphates and potassium salts to the chlorides and sodium salts; and the acidity or alkalinity of cows' milk is influenced by their food. As a rule, I believe it is alkaline.

I am in the habit of directing, as food for newborn infants, a mixture resembling colostrum—one part cows' milk to two or three of water, with a little sugar, for infants of two to six months; equal parts of milk and water, warmed and sweetened, for infants over six months; two parts milk and one of water, etc. As to quantity and frequency, much must depend on the child.

Dr. Parish: I cannot pass judgment upon the chemical question, but the matter of substitutes for human milk is one that I am brought face to face with every day in private practice, and in public institutions. I have had but little successful results with any of the prepared foods in the market, except condensed milk. I have frequently been called to see infants who have been seriously sickened by the use of such foods, or by other ill-advised articles of infant diet.

If I have care of a child from birth, who is to be brought up without human milk, I begin with condensed milk; during the first few days I direct that one heaped teaspoonful should be dissolved in thirty teaspoonfuls of water; about the end of the first week one teaspoonful of the milk in twenty-five of water; at the end of a month one teaspoonful in twenty of water; at about the end of the second month I have added one-fourth cream; at the eighth month a change is made to cows' milk, diluted with one-third water, with occasional use of beef-tea, etc., according to the age.

I do not think a child using condensed milk for sixteen or eighteen months continues to thrive so well as if the method stated is resorted to. Cows' milk is unsafe for young infants in the cities.

The addition of cream is advantageous by overcoming constipation accompanying the use of condensed milk, and by contributing very perceptibly to the nutrition of the infant.

If a child, dependent chiefly on cows' milk, is taken sick, with bronchitis or any febrile disease, or with any digestive derangement, I recur to condensed milk as a sick diet.

Dr. Meigs, in closing the discussion, said: I do not see that anything has been said to disprove what I have advanced, which was, substantially, that if analysis shows the water, fat, sugar, and salts of milk to equal a certain amount, then the casein can only equal the difference between that amount and the total quantity of milk taken. We know what these four substances are, and can identify and estimate them. What casein is, however, is not yet fully understood; but we cannot escape from the conclusion as to its small amount in human milk, unless the process of analysis be shown to be erroneous in regard to some one of the other four constituents. I have noticed, incidentally, that the clear ethereal solution of the fat of milk sometimes lets fall a precipitate after standing. This I at first thought to be casein, but as it melted when warmed, it must be some one of the forms of fat, but is insoluble in ether.

I do not think that the specific gravity is any guide as to the composition of milk—Mr. Wanklyn has shown its utter unreliability; nor do I think that we can distinguish the different amounts of sugar or casein in milk by the difference of taste or amount of coagulum. Milk-sugar has very little sweetish taste. The composition of milk is tolerably constant; it is not subject to such large variation within normal limits as urine is. Milk does vary much in its amount of fat. That first drawn from a woman who has not nursed her child for some hours, will usually contain only two or three per cent. of fat, while that taken just after nursing may contain nine per cent.

As regards the amount secreted by women,

very absurd statements—much below the proper figure—have been made by some of the older authorities, but Dr. John F. Meigs succeeded in one case in getting as much as three pints in twenty-four hours.

The salt which exists in largest quantity in milk is sodium phosphate. Cows' milk is almost always acid, while human milk is almost always alkaline in reaction.

Most authorities agree that cows' milk must be diluted when used for infants. Why is this, if not because the casein is less in human milk?

I agree with Dr. Parish that most of the prepared foods are not good. Condensed milk is largely used by physicians in this city, and I believe its success is due to the fact that it gives only about one per cent. of casein, as usually directed to be given. Condensed milk contains about fifty per cent. sugar. It is not unlikely that some of the milk-sugar is removed from it. Milk-sugar and casein are entirely insoluble in absolute alcohol, and alcohol will only take up very small quantities of milk-sugar as it becomes dilute, and only when it is very dilute will it take up any considerable amount.

My effort has been to place the demonstration of the amounts of the different constituents of human milk, so far as possible, upon a mathematical basis; and unless it can be shown that the estimate of some one of the four constituents—water, fat, sugar, or salts—is wrong, then it has been proved that human milk contains only the small amount of casein stated.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Dr. John H. Packard read a paper entitled

Report of a Case of Abdominal Tumor Somewhat Resembling Pregnancy in a Young Married Woman.

I venture to hope that the following report of a case presenting some unusual features may be of sufficient interest to warrant me in bringing it before the College:

Mrs. G., æt. 21, a very slim and delicate-looking woman, consulted me on the 21st of July in regard to a slight and uniform abdominal enlargement, which had been first noticed by her shortly after her marriage, about three months previously, and had been gradually and steadily increasing. She menstruated regularly every month, and had had no nausea. Neither the breasts nor nipples showed any change from the virgin state.

There was no tenderness at any point in the abdomen, and the appearance and feel of the swelling were very much such as would be presented in the early stages of pregnancy.

On the 26th I saw her again, and made an examination per vaginam. The os uteri was soft, and the cervix was of some length; but there was a bulging above, as if the uterus contained a mass partly solid and partly liquid. I did not, of course, think it right at this time to introduce a sound, as, in spite of the absence of rational signs, the presumption seemed to me to be in favor of pregnancy. One fact seemed to militate against this view, viz., that she rather lost than gained flesh.

I declined to express any opinion as to the

character of the swelling, but told the husband that my hope was that the case would prove to be one of pregnancy, as it was likely otherwise to be very grave.

There was a good deal of pain on either side of the hypogastrium, apparently due to tension of the muscles; this was temporarily relieved by the use of chloroform liniment. She had very little appetite, and I gave her a tonic composed of nuxvomica and gentian.

The swelling continued to progress steadily, and on September 13 she presented the appearance of being about the middle of the fifth month of gestation. The hypogastric pain troubled her greatly, and was only allayed for a very short time after each application of the liniment.

At the desire of the family, I now asked and obtained the advice of Dr. Ellwood Wilson, who saw her with me on September 15.

In the forty-eight hours which had elapsed between my previous visit and this one, a very marked change had taken place. The abdomen had become greatly enlarged, its walls forming one curve from the ensiform cartilage to the pubes; there was very decided fluctuation, and percussion showed an area of dullness, which was attributed by Dr. Wilson to the existence of a cystic tumor connected either with the Fallopian tube or with the broad ligament. A sound was introduced into the uterus, the cavity of which was found to be unoccupied. Dr. Wilson advised the drawing off of the liquid, which was accordingly done by aspiration on the 17th. More than a gallon of ropy yellow liquid, somewhat deeply tinged with blood, was thus removed; the flow then ceased, and the end of the canula encountered a solid substance, apparently a septum of considerable thickness. Upon the withdrawal of the instrument, a fresh flow took place, the liquid spouting out from the orifice to a distance of several inches. When this subsided, the abdomen, which was much less tense, was covered with raw cotton, and a bandage carefully and firmly applied.

During the operation, the patient became quite faint, but rallied after the administration of a little brandy and water. In the evening her temperature arose to 103.5°, but before morning it fell to about 100°. She slept very little, and complained of much pain, due partly to the stiffening of the cotton and bandage by the agglutination of some of the liquid which oozed from the belly. On examining the wound in the morning, it was found closed.

The following evening the temperature again rose to 103.5°, but subsided again before morning, and was not thereafter above 99°. Yet her condition was unsatisfactory; her face was much pinched, and anxious; she had very little appetite or ability to take food; at times her mind wandered slightly, and she slept but little. Vomiting occurred frequently, and she was seldom free from nausea. Her bowels acted regularly; her urine was free, and normal in every respect. Her pulse varied, but was generally from 110 to 120.

Beef-tea, milk, with brandy and lime-water, and champagne, were given at as short intervals as the stomach could bear them, and at stated times. External warmth was carefully kept up.

It was determined that should symptoms of

peritonitis present themselves, ovariectomy should be at once resorted to.

A portion of the liquid was submitted to Dr. H. F. Formad for examination, and his report, which was not received until some time after the case had terminated, was: "I think it very doubtful that it comes from an ovarian cyst, the fluid showing very little epithelium, and very few of the ovarian cells of Drysdale."

September 23, her condition was very much more favorable; her mind was composed and even cheerful; her pulse and temperature good. Some food had been taken and retained.

On the 24th her state was much the same, and it was thought proper to entertain the idea of an operation for the removal of the supposed ovarian tumor. In the afternoon Dr. Agnew saw her with Dr. Wilson and myself, and it was decided that the attempt should be made on the following day.

Accordingly, on the 25th, at noon, ether was administered by Dr. G. P. Sargent, of Bryn Mawr, and in the presence of Drs. Wilson and Agnew, I opened the abdomen by an incision in the median line. After dividing the wall I came to what seemed to be a cyst, and passed in an ovariectomy trocar, when a very free evacuation of liquid, straw-colored and ropy, but clear, took place. It was now apparent that the liquid was contained in the peritoneal cavity, and that there was a large solid mass lying among the intestines. This tumor was soft and doughy, like a placenta; it seemed to belong to the mesentery, since although somewhat movable, it was firmly attached to the posterior wall of the abdomen, rather high up. The surface of the mass having been slightly lacerated, there was somewhat free bleeding, which was checked with some difficulty by ligation with carbolized catgut, and by the application of a caustery-iron.

The wound was now closed with two large pins and a ligature cast around them, and with metallic sutures; a sheet of raw cotton was applied over the whole belly, and secured by a bandage.

The patient rallied considerably, and after the effects of the ether had passed off, became quite sensible; but she soon began to sink, and died on the 27th, about forty-eight hours after the operation.

No autopsy could be obtained, so that the exact nature and connections of the tumor must remain a matter of conjecture.

The notable points in the case now detailed seem to me to be the occurrence of a solid tumor, probably of malignant character, and apparently connected with the mesentery, in a young woman recently married; its resemblance in its physical appearances to the pregnant womb; the very sudden change that took place by fresh effusion into the peritoneal cavity, and the obscurity which even then existed as to the real nature of the case. Even with the most accurate diagnosis, effective treatment would have been out of the question; and I cannot but think that my suspicion of pregnancy, erroneous as it proved to be, really prolonged the patient's life, which would have been almost necessarily sacrificed by earlier interference.

—Prof. DaCosta teaches that arsenic, in small doses, is very useful in chronic gout.

EDITORIAL DEPARTMENT.

PERISCOPE.

Primary Cancer of the Gall Bladder.

Dr. A. H. P. Leuf reports this case in the *Proceedings of the Medical Society, County Kings*, February, 1884:

The following case occurred in the service of Dr. Geo. H. Kuhn, at St. Mary's Hospital. The accompanying meagre history is all that could be obtained, and is furnished by I. H. Platt, M. D., House Physician at the hospital:

Female; æt. 70 years; English; married; and housekeeper.

She was sent up from the down-town St. Mary's, without a history. She had been feeling badly since last winter, and for the last two months has been jaundiced. At time of admission she complained of great pain across the abdomen, also seemed very weak. The abdomen was enlarged. The liver extended down almost to the crest of the ilium and hard masses could be felt projecting from it by palpation. Gave M. viii. of Magendie's solution which partially relieved the pain. She sank rapidly during the night and died the next morning at 9.30 o'clock.

Autopsy.—Body markedly emaciated. Average rigor mortis. Deep lemon-yellow color of skin all over the body. Both lungs were emphysematous (senile) and hypostatically congested. The heart was flaccid and contained a little blood. The stomach was about half full of liquid food and gas. Its pyloric portion was adherent to the gall bladder and hepatic end of the transverse colon. On raising the liver from the stomach, a small piece of gastric wall, about .5 cm. in diameter, stuck to the liver and left a corresponding opening in the stomach. This hole was a post-mortem accident, but must have happened ante-mortem in a short time had the patient lived a little longer. The gut was contracted, and the colon was agglutinated as just mentioned. The liver was very much enlarged, its right lobe extending down to the anterior superior iliac spine, and the left as far down as the umbilicus and over against the ribs of the left side. It contained cancerous nodules varying in size from a pin's head to 6 cm. in diameter. The gall bladder was very long, and contained eighteen good-sized stones. One was different from all the others in its being dome-shaped, with a flattened base and granular surface. It occupied the distal end of the gall bladder, and was about 2 cm. in diameter at the base. The free end of the gall bladder was normal, but its narrower half was thickened so as to measure fully 2 cm. through any part of its upper wall. This part of the viscus was almost as firm as cartilage, and it was at this point that the gall bladder, stomach, and colon were adherent. The spleen was normal in size and otherwise. The pancreas was slightly indurated at the head. The right kidney was congested and the left anæmic. The uterus contained a hard cancerous nodule in its anterior wall at the cervicocorporeal junction. It measured about 2 cm. in diameter.

It is probable that the congestion of the right kidney was secondary and due to the hepatic disease, and that the anæmia of its fellow was dependent upon the poor general health of the patient.

Hepatic carcinoma may be either primary or secondary. The former is rare, the latter occurs frequently by metastasis. The variety is usually scirrhus, but sometimes is encephaloid. When primary, it appears as a large mass surrounded by smaller ones, and when secondary, large and small masses occur indiscriminately throughout the organ. Primary cancer of the gall bladder is more common, and it is almost invariably of the scirrhus variety, as might be supposed *a priori* from the structure of this viscus. In this form of cancer of the gall bladder the cavity is diminished at the same time that general enlargement takes place, *i. e.*, there is a thickening of the wall internally and externally. The cavity is often filled with calculi (as in this case). When the bladder is thus affected, it forms adhesions to all the structures with which it is brought in contact, and subsequently induces in them locally the same trouble. The liver is the most frequent seat of secondary carcinoma. Cancerous changes in the liver are most marked in those parts adjacent to the primary infecting focus, provided that it is in contact with the liver, as the stomach, hepatic flexure of the colon, gall bladder, etc. Umbilication is also a marked characteristic of the cancer nodules found upon the surface of the liver. It is caused by a breaking down of the centre of the cancerous mass and its consequent absorption, thus resulting in a falling in of the middle of the surface of the moplasic nodule, while the healthy margin preserves its original relations. The liver is also larger in the encephaloid variety of cancer than in the scirrhus variety. The reason for this is obvious, as the growth of the former is more rapid than of the latter, and in this wise allows the affected organ to attain a larger size in a given time, *i. e.*, before death. Hepatic carcinoma is also peculiar in that it invades branches of the portal vein, forming inward projections having a warty appearance and a sessile attachment. Sarcoma hepatis is frequently said to exist when the affection should properly be classed as a carcinoma. Sarcoma of the liver, it is well to bear in mind, is very rare, only occurring as a secondary formation, and then almost always derived from the melanotic variety.

The Treatment of Habitual Constipation.

Dr. F. P. Atkinson thus writes in the *Practitioner*, January, 1884: I suppose there is no derangement of the system we are more frequently called upon to treat than habitual constipation; and though all kinds of medicines are suggested for its relief, they rarely produce more than temporary benefit—and it is difficult to see how the result can well be otherwise, while the root of the evil remains untouched. Now by far the more numerous subjects of this disorder are women;

and as they do not seem to know that regularity is essential to the performance of every one of nature's operations, they appoint no stated times for trying to get the bowels relieved, but trust to receiving intimation when the rectal accumulation and distension can be borne no longer. This method of action may and does answer fairly well for a time; but nature gradually gets upset, the sensation of the lower bowel becomes blunted, and at last it ceases to respond to the ordinary stimulus. Then aperients are regularly resorted to, and though these act fairly well for a time, they gradually have to be increased in strength and frequency. Now, as regards the treatment, the first thing to be accomplished is of course to get the rectum well relieved; the next, to get the actions to take place at fixed times; and lastly, it is necessary to get more tone imparted to the muscular tissue of the bowels, so that the regularity of action may be helped and also maintained. In order, then, to get the bowels relieved in the first instance, it is as well to give five grains of both compound colocynth and compound rhubarb pill at bed time (this rarely requires to be repeated), then to take a tumblerful of cold water the next morning on waking, and repeat it regularly at the same time each day. Should the bowels remain sluggish for some time, the same quantity of water may be taken daily before each meal. Supposing no action takes place on rising or shortly after, a small injection of warm water may be resorted to. After each movement of the bowels, a small hand-ball syringe of cold water should be thrown into the rectum and retained. A soup-plateful of coarse oatmeal porridge (made with water and taken according to the Scotch method, viz., by filling half the spoon with the hot porridge and the other with cold milk) each night at bed-time, or even every night and morning for a time, is often a very great help. But above all things, it is necessary for the patient to *try* and get relief at a certain *fixed* time regularly every day. If these directions are strictly carried out in their entirety, the evil, even if it has been of long standing, will generally be corrected, and the patient will improve in health and appearance. Of course, where the constipation results from exhaustion of the nervous system (such, for instance, as is brought about by self-abuse), the special cause has to be taken into consideration, and such treatment adopted as is suited to the particular necessities of the case.

On the Treatment of Hay Fever and Allied Disorders.

In a very valuable paper on this subject in the *American Journal of the Medical Sciences* for January, 1884, Dr. Harrison Allen claims that the means of effecting the cure of this hitherto considered incurable disease is simply to overcome the tendency to obstruction in the nasal chambers.

The symptoms of hay fever are always associated with some degree of obstruction of one or both nasal chambers. A cause of this obstruction is dilatation of the blood-vessels. There is no doubt that the local phenomena are in most instances the same, and that the multiform related symptoms, such as injection of the eye, headache, malaise, asthma, etc., are due to reflex vasomotor

disturbances. But many patients report for treatment who exhibit swelling of the nasal mucous membrane, occlusion of the respiratory passages, and mucoid or semi-purulent discharge, without any of the related reflex phenomena. Yet a third and intermediate group exhibit perhaps a tendency to turgescence of the mucous membrane, together with one or more of the more common constitutional symptoms of typical hay fever. Indeed, there is nothing peculiar to the disease just named save its sharply defined periodicity, particularly in that phase of it where the periods of recurrence happen to coincide with the time of fruitage of certain plants, or the gathering of certain crops. In a small group of cases, where, in addition, other signs and symptoms become prominent which would invalidate the above proposition, Dr. Allen is inclined to attribute them to mental impression—in some of the varied phases of hysterical or neurotic excitement.

Or the case may be stated in different language, as follows: In an imperfectly defined group of cases of nasal catarrh, a sensation of sudden obstruction of one or both nasal chambers is a conspicuous symptom. This sensation is accompanied by a constant change in the chambers themselves, viz., engorgement of the membranes over the turbinated bones, producing pressure against the septum and occlusion of the respiratory passages of the nose. The sensations are recurrent, but vary greatly as to the time of the day or the season of their return. With some patients they are nocturnal, and are associated with the recumbent position; with others they occur after meals only; with some they occur in the summer season; with others yet again, in the winter. The sensations may be confined to either chamber, or be present in both. In aggravated cases they are associated with numerous reflex symptoms, among which may be mentioned lachrymation and hyperæsthesia of the conjunctiva, headache, and asthma. Patients having a disposition to obstruction during the summer and autumn report themselves as suffering from "hay fever;" while those having alternating attacks in the right and the left chambers report with "nasal catarrh."

The cases so far studied exhibit one feature in common, viz., that the inferior turbinated bones lie well above the plane of the floor of the nasal vestibule. In many persons, not the subjects of "hay-fever" and allied disorders, the lower free portion, including, of course, the inferior border of the bone, lies below the plane of the floor of the nasal vestibule; and in ordinary inspection the inferior meatus is out of sight.

It will thus be seen that the mucous membrane, which is known to be the most erectile, is also the most exposed to irritation from extraneous substances, and to changes in the temperature of the surrounding air.

The conclusions to be drawn from the study of the six cases reported by Dr. Allen may be summarized briefly as follows:

1. That the treatment of all conditions of obstruction in the nasal chambers, no matter from what cause arising, can be successfully carried out by destroying the causes of obstruction. If the cause be an overgrowth of bone-tissue, if must be filed, sawed, or drilled away. If it be caused by a deviated cartilaginous portion of the septum,

such portion must be re-set in a new place. If, as is often the case, it is due to periodic turgescence of the mucous membrane, or the resulting secondary hypertrophies, such growths must be destroyed, either by the galvano-cautery, by the snare, or by caustic acids.

2. That the treatment of hay-fever and allied periodically-recurring nasal affections in no way differs from the treatment of other nasal diseases accompanied by obstruction, and that the treatment may be conducted during an attack as well as in the intervals between any two attacks.

Foot-measurements in New-Born Children. A Contribution to the Treatment of Pelvic Presentations.

The *Am. Jour. Obstet.*, January 1884, says that Gonner, in the *Ztsch. f. Geb. u. Gyn.*, ix., 2, complains that the most systematic authors in obstetrics say too little in regard to the difficulties which accompany extraction in breech presentations, whether these difficulties be primary or secondary to turning. The importance of knowledge upon this subject can be appreciated when we remember its bearing upon prognosis in respect to the life of the child. We have methods sufficiently accurate for ascertaining the dimensions of the mother's pelvis, as those of the child's head; but nothing has heretofore been offered which would enable us to get a good general idea of the size of the fœtus in utero. Ahlfeld's method with the instrument (Tasterzirkel) devised by him is inaccurate, and gives useless results. In order to obtain an approximate idea of the size of the child, we must get an accurate measurement of some part which is accessible, and this part must bear a tolerably constant relation to the size or proportions of the entire body. Such a part in breech presentations is the foot. In order to ascertain whether the length of the foot stood in any particular relation to the weight of the child, measurements were taken in one hundred consecutive births, during the year 1881, at the Basle obstetric clinic. The measurements were made immediately post-partum, with a wooden instrument similar to that which is used as a measuring-stick by shoemakers, and in a similar manner. In a procedure which is apparently so simple, great pains are necessary, for the differences in the length of the feet of new-born infants are slight. As a result of the author's labors in the cases mentioned, the conclusion reached was that for a length of foot of eight centimetres a total weight of three thousand grammes might be expected as a rule; also that a length exceeding eight centimetres made it probable that the child's weight exceeded that of the average mature fœtus, and that extraordinary difficulties in extraction might be expected. By considering, in addition, the measurements of the maternal pelvis, data are afforded, says the author, which will enable us to prognosticate the birth of a living child, or the necessity for a destructive operation. It must be borne in mind always that these calculations have no reference to hydrocephalic children, and those who are subjects of other deformities. A foot which measures seven and six-tenths centimetres in length presupposes a child of moderate size; a length of less than seven and three tenths centimetres presup-

poses an immature fœtus. In the tables which are given by the author, a tolerably constant difference in weight is observed, between male and female children, in cases in which the feet of both sexes are of the same length, the females being the heavier; but this is not considered of any especial importance in an obstetric point of view. The occupation of the parents, also, has something to do with the size of the hands and feet of the offspring, and as the measurements in the tables referred to were taken upon children in the poorer, or working classes, the relative weights are, probably, larger than would obtain among the children of those who are not habitually engaged in severe manual labor. Race and national peculiarities may also require consideration, and it is to be hoped that the subject will be worked in other fields, for the perfection of the desired statistics.

Tubercle and its Resistance to Antiseptics.

The *Med. Times and Gaz.*, December 29, 1883, says: In a previous number of this journal (vol. ii., 1882, p. 669), a brief notice will be found of a paper which appeared in the *Revue de Médecine*, by M. H. Martin, demonstrating the extraordinary power of resistance enjoyed by the tuberculous virus against high temperatures and the effects of alcohol. In the October number of the same periodical there is a further communication from the same author, in conjunction with his deceased teacher, M. Parrot, detailing the results of experiments with salicylic acid, sulphate of quinine, corrosive sublimate, carbolic acid, creasote, bromine solution, and oxygenated water. The plan adopted was to take a portion of the tuberculous viscera of an animal that had just died of tuberculosis, and place it in the solution to be tried. After it had been left a varying length of time in such solution, inoculation-experiments in fresh animals were made, to see if it would induce tuberculosis. The solutions used varied in strength from one in 5,000 to one in 500, and it may be said that none of the above reagents succeeded in destroying the infective property of the tuberculous material with anything approaching constancy. The authors conclude their paper with the following practical remarks: "It is thus clearly proved that the vitality of the tuberculous virus is considerable. In therapeutic doses the antiseptic agents actually in use are powerless to destroy it, and the daily failures in practice seem, so to speak, borne out by what has already been shown. Again, it is perfectly clear from our experiments that the antiseptics in daily use are powerless against it. We wash instruments in alcohol or in a solution of carbolic acid (1 or, at most, 2 per cent.); we moisten the walls or the floors of our hospitals with the same solution; and are quite willing to believe that, in consequence of this, all germs, including those of tuberculosis, are rendered inert. It is easy to understand that such an illusion may bring about grave consequences. Even the sulphurous vapors advised by M. Vallin, even the vapor of bromine, which is still more caustic, can only act when tolerably concentrated and after some length of time, and in this case their employment becomes dangerous and difficult. - The only agent which

germs, be they what they may, cannot resist for a single moment, is fire. Now, we know that at 100° the tubercle loses its infectious property in a very little while; and a temperature, even dry, of 120° to 125° destroys this power almost instantly. We must conclude that a heated stove is the only certain and practical purifier of instruments for surgical or experimental operations, for clothing, linen, and dressings; in short, for all objects whose shape and size admit of their being introduced into it. As regards the walls, floors, etc., of private rooms or hospital wards, it would be possible, it seems to us, from time to time, to submit them to the action of a current of air heated to about 125°, which, being brought by means of suitable portable tubes, and distributed just as one directs a jet of water from a pump, would dry and calcine the infectious germs hanging about the plaster, pictures, or woodwork, without sensibly damaging them." Such are the precautionary hygienic measures the authors recommend for adoption against the contagion of tuberculosis.

The Treatment of Acute Nephritis.

The *Lancet*, December 29, 1883, says:

There are few diseases which give rise to more anxiety in their treatment than those in which the kidney is concerned. With regard to both the precise pathology of renal inflammation and the therapeutics of this disease, much unquestionably remains to be determined. True, there are well-recognized principles to be followed in practice—namely, first, to give the inflamed organ rest, and therefore neither to irritate it by so-called diuretic remedies, nor embarrass its action by giving nitrogenous food; second, to see that the skin, which may be regarded as the *alter ego* of the kidney, is called into vicarious action. In spite of these guiding principles, however, acute renal inflammation remains often the despair of the physician. Dr. Aufrecht, of Magdeburg (*Berlin Klin. Wochenschr.*, December 12), who, as is well known, has paid much attention to the pathology of nephritis, advocates most forcibly the adoption of an expectant line of treatment, in which dietetics play an important rôle. He absolutely discountenances the prescription of diuretic and diaphoretic drugs, and regards it as not good practice to encourage diaphoresis by hot baths or heated air. We go with him in his condemnation of diuretics, or of those salts which act notably on the kidney, and which we are persuaded are often given unnecessarily, and perhaps with injury; but in his objection to diaphoresis he seems on less secure ground. His plan consists in the administration of neutral salines, as bicarbonate of soda, which may be replaced by iron in the later stages, when the anæmia evoked by the albuminuria appears. The diet at first must, he says, be wholly vegetable, in the form of vegetable soups, and starchy and saccharine foods; even milk is to be avoided till after the first or the second week of the acute attack. This rigid regimen is necessary to diminish the special function of the kidney—elimination of nitrogenous matters. He quotes Lichtheim and Senator in support of this doctrine, which recognizes in the defective elimination of the kidney a much

graver incident than the outpouring of albumen, and which, therefore, emphasizes the necessity of reducing to a minimum the ingestion of proteids. Aufrecht details one case (of scarlatinal nephritis) where suppression of urine lasted for eighty hours, and where this expectant treatment was followed by recovery. He mentions another, where the anuria lasted for fourteen hours; and he asserts that under the diuretic and diaphoretic plan of treatment cases such as these would almost certainly have succumbed. To avoid misconception, we should add that he prescribes a warm bath occasionally in such cases, but never to the extent of inducing profuse diaphoresis, and that he makes no mention of free purgation. Probably he would discountenance this, as another measure of harmful interference.

Creasote in Diseases of Air Passages.

Dr. Pick, of Coblenz, says (*Deutsche Med. Wochenschr.*, 1883, No. 13), that the action of creasote in consumption, recently much extolled by the French (Bouchart and Gimbert), as well as the successful experiments of Fränzel and Curschmann, induced him to employ this much discredited remedy in a series of cases, and to make a summary of the results. Creasote was given by the author both internally and externally. For external use he employed a mask which, being a modification of Hausmann's apparatus, could be worn by the patients without much difficulty, and even during the night. The creasote was dropped on the cotton-wool in the mouthpiece, and was inhaled by means of deep inspiration. The apparatus has the advantage over Hausmann's that the nose remains free, and the troublesome irritation of the nasal mucous membrane is avoided. Dr. Pick gave the creasote internally either with cod-liver oil, or according to the French formula: Kreasoti 13.00, tinct. gent. 30.00, spirit. vini rectif. ad 250, vini Malag. ad 1,000. The drug was well borne by the patients both internally and in the form of inhalation, and Dr. Pick speaks of one case where there was a decided antipathy to cod-liver oil, but where it was taken quite well in the above-mentioned combination. Gastric disturbances or toxic effects were seldom perceived. Among the cases treated by the author was one of croupous pneumonia passing into gangrene, thirteen of tuberculous infiltration in persons with hereditary taint, and one of sudden hæmoptysis after long-standing catarrh of the lung. The results were very good in all sixteen cases; after a short use of the drug, diminution of the cough, considerable reduction of temperature, improvement of the general health, and decrease in the expectoration quickly ensued; and the hæmoptysis mentioned above, which had not yielded to a fourteen days' treatment with ergotin, was speedily checked by a few hours' inhalation of creasote. This may, perhaps, be attributed to the styptic action of the creasote, which, besides its disinfecting and antipyretic properties, coagulates albumen and contracts the capillaries. A lasting effect was, however, observed to follow the employment of creasote only in catarrh of the apex, or in commencing infiltration. In advanced phthisis, where extensive disintegration of tissue with great diminution of strength was already

present, the only lasting result was the alleviation of isolated symptoms. Dr. Pick lays particular stress on the quality of the creasote, and attributes its actions only to that got from beech-wood tar, in contradistinction to the kind more frequent in commerce, obtained from coal-tar, whose qualities, so far from being useful, only set up gastric disturbance.

Thirteen Cases of Herniotomy for Strangulated Hernia.

Before the Medical Society of London (*Brit. Med. Jour.*, December 15, 1883), Mr. Keetley read a paper on this subject. Of these cases five were femoral, seven inguinal, and one umbilical; three died. Of course, such small numbers were of no value statistically. For example, at St. Bartholomew's, in 1876, only two cases of inguinal herniotomy died out of ten, while, the very next year, six died out of seven. After discussing the probable cause of death in his two fatal cases, which he attributed in one case at least to septic infection, the author said that, with one exception, the chief indications of practice of antiseptic ovariologists should be borne in mind by the herniotomists. The exception was the rule, that, in cases of extravasation of blood or other fluid, the abdominal cavity should be thoroughly sponged out, and rendered aseptic. It was absolutely essential that, in herniotomy, all extravasation into, or septic contamination of, the peritoneal cavity should be prevented. To attain this end, he advocated the practice now coming into vogue, both on the Continent and in this country, but especially in Liverpool, of tying the neck of the sac high up as soon as the strangulated bowel, etc., has been reduced. Thus the whole operation-wound, including even the notch in the edge of the femoral inguinal ring, would be entirely cut off from the peritoneal cavity. However, sometimes after cutting the constricting edge, the surgeon found it a work of difficulty and slowness to reduce the swollen intestines. In the meantime, hemorrhage was very likely taking place into the peritoneal cavity. Within certain limits, strict antiseptic precautions made this a matter of indifference. Beyond these limits, it might become a serious matter. Hence, in such cases, Mr. Keetley suggested a second incision of the linea alba into the peritoneal cavity, just above the pubes, merely large enough to admit two fingers, with the help of which the intestine, etc., could be pulled back into the abdomen. When the hernia was known to be quite recent, it would be justifiable to attempt to reduce it by this proceeding alone, with an incision over the hernial aperture. It was so much more rational to attempt to pull back than to push back a soft and flexible loop through a tightly constricting hole. The same principle had long ago been applied to umbilical herniæ by Crompton, of Birmingham, and more recently and successfully by Annandale and Bennett May. But Mr. Keetley had conceived the idea quite independently, and without at the time knowing of these cases. He had not yet himself met with a case in his judgment demanding an application of this plan of a suprapubic incision. He had done Crompton's operation in the case of umbilical hernia which died.

REVIEWS AND BOOK NOTICES.

BOOK NOTICES.

The Field of Disease. A Book of Preventive Medicine. By Benjamin W. Richardson, M. D., F. R. S., etc., Philadelphia: H. C. Lea's Son & Co., 1884. Cloth 8vo., pp. 734.

With his accustomed erudition, and in his wonted easy style, Dr. Richardson has here presented the doctrines of the etiology and prophylaxis of disease as he understands them. He is, as always, full of instruction, and his exposition has no lack of clearness, but, as always, he is the very earnest advocate of his personal opinions, which are often either in antagonism to those of most members of his profession, or are as yet too slightly supported by evidence to justify any such positive statement. To begin with, his averment (which is quoted with applause by his American publisher in a prefatory note), that the idea that diseases can be prevented is of modern times, and "practically of the later two-thirds of the present century," could be made only by one who is ignorant of the History of Medicine. Our modern methods of prevention are many of them new, but enlightened physicians in all ages have earnestly preached both personal and general prophylaxis.

Again, Dr. Richardson's indiscriminate attacks on all alcoholic beverages are so far from being tempered with the moderation of science, that they cast general doubt on the power he has of framing an unbiased judgment.

The plan of the volume is as follows; it is divided into three parts: The first treats of general diseases, local diseases, and diseases from natural accidents. In this part the diseases are classified according to the accepted English nomenclature. The second part or book treats of acquired diseases, which are divided into those from poisons, from physical agencies, and from mental agencies. The third and last book is a summary of the origins, causes and preventions of disease. This is the most interesting part of the treatise, and is that to which the reader will turn first, in order to gain as quickly as possible the views of the author. It contains a vast amount of solid, valuable hygienic information.

In England, this work was published with a preface recommending it to the non-medical public. It is, we think, much too technical for their use, and is better suited to the physician's office than the family library.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

THE ORIGIN OF THE LATE CHOLERA EPIDEMIC.

Dr. W. G. Hunter, retired Surgeon General of the Indian Army, delivered an address recently before the epidemiological Society, in London, on the recent epidemic of cholera in Egypt, which contains some exceedingly valuable points and much instruction. As we are ready to believe, his arguments all plead strongly for cleanliness as our most available and effective prophylactic against the invasion of cholera.

He very convincingly states that the disease was not carried into Egypt from without, but that, owing to the wretchedly unsanitary condition of the people of Egypt, the disease is more or less prevalent all the time, and on account of unusually unhealthy surroundings during last summer, it increased so much in violence and in number of cases as to constitute a most terrible and fatal epidemic. To give some idea of the filthy condition of this historic old country, we will make some extracts from his address:

"The larger majority of the people drink the water unfiltered, and generally before it has been allowed time to deposit. It is said that they prefer it in this condition. In Cairo the quality of the water supply is indifferent. At the water-works there is but one settling tank, and, as it is in constant use, it can never be cleaned.

"The large amount of mineral matter contained in Nile water, while settling, carries down with it no inconsiderable quantity of the organic substances held in suspension in the water, and must lead to rapid fouling of the tank. Filtration is effected by gravel and sand. In the Ismailia quarter, that is, the fashionable part of the city, and in the Boulac quarter also, no attempt is made to filter the water, but it is supplied as obtained from the Nile. Close to the intakes of the Cairo water-works, where some slight efforts, it is presumed, would be made to prevent pollution of the water, I have seen human and other animal excreta, fresh and stale, lying about in various directions, and men and women bathing, and washing their soiled clothes in the river. This was by no means an uncommon sight.

"In Alexandria, an attempt has been made to establish a sewerage system, but, as in most things Egyptian, a very defective one. In the first place, it is but partial; in the second, it possesses radical defects of construction, and the outlets, some twelve or more in number, pour their contents on

to the beach directly to windward of the city. The sewers are, moreover, unventilated, such ventilators as existed having been sealed up about five years previous to my visit in August last. The privies of the houses are in direct communication with the sewers.

"As a specimen of the quality of the water used by the villagers in Egypt, I would, in passing, call attention to a report made to me by Mr. Honman, one of the twelve medical gentlemen sent to Egypt by Her Majesty's Government for service during the epidemic. This gentleman was in charge of Mehallet-el-Kibir, a town of about 28,000 inhabitants, situated to the north of Tanta, midway between the Rosetta and Damietta branches of the river. Mr. Honman states in his letter, dated August 30, 1883: 'The town has three mosques; the drain from one running through the town, quite open, and with three feet of filth at the bottom. This discharges itself into a pool of water at the back of the town, which is used by the people for domestic purposes, and as drinking-water for their cattle. The other two mosques drain in a like manner into pools outside the town, and they also are used by cattle and for domestic purposes. The stench from these drains can be smelt all over the town.'

"During the past year the water-ways were more than ordinarily polluted by carcasses of cattle which had died from typhus being thrown into them, in order to evade a tax of five francs per head for their burial, which the poverty-stricken fellaheen were quite unequal to pay. It is notorious that many of the fellaheen were reduced to such straits as to be forced to feed on the carcasses of cattle which had died in this way. The number of carcasses and portions of carcasses in a far advanced state of decomposition removed from the Damietta branch of the river amounted to upwards of 1,500, a number considerable in itself, but insignificant as compared with the thousands which must have been thrown into the river. The losses in cattle occasioned by the 'epizootic' weighed heavily on the fellaheen, and reduced them to strange and curious expedients to till the soil.

"The villages are collections of mud-hovels, in which, with the human family, reside all their domestic animals, as pigeons, fowls, asses, goats, and perhaps a camel. In no towns, so far as I know, are there public latrines, except those belonging to the mosques, which are quite inadequate to meet the wants of the people, who are driven to the streets, gullies, and open spaces for natural purposes. This remark applies equally to cities like Cairo and Alexandria."

These extracts are sufficient to demonstrate the terribly unsanitary conditions that surround the people of Egypt, while Dr. Hunter's thoughtful and logical address will make any unprejudiced man believe that filth is the etiological factor of cholera. From it we must derive the valuable lesson, that in cholera as in all other epidemic diseases, our great safeguard lies in scrupulous cleanliness, both of person and surroundings.

FACTORS DECIDING THE SEX OF THE OFFSPRING.

Many a theory has been proposed—and exploded—concerning the conditions which decide the sex in the offspring. Those interested in the raising of horses, cattle, pigs, etc., have doubtless made a more practical progress in this question than physicians have done with regard to the human being. It is not rare to notice that a sheep-grower, for instance, will raise only ewes, if it is his intention to do so.

Recently, Dr. K. Düsing has studied the factors deciding the sex of the foetus, and published (*Centrbl. f. d. Med. Wiss.* 45, 1883,) an interesting article concerning his results; and as the subject has an undoubted vital bearing upon the propagation of the human race, we will not withhold it from our readers.

Fiquet made first the observation on cattle, that those animals that sexually were very much occupied, produced more individuals of their own sex, and D. explains this by saying that the male whose genital apparatus is frequently used, is provided with fresher sperma, so that fecundation ensues with comparatively young and active spermatozoa. In such a case more male offspring are produced; while a male whose sexual organs rarely perform their function, will give rise to more female offspring, because his spermatozoa are older, weaker. In the female the same holds good, the ova being earlier (fresher) fecundated, and a predisposition to the female sex takes place. As a natural consequence, it follows that the more there is a want of individuals of one sex, the more their sexual functions are required—the quicker, the younger their sexual product is

made use of—the more members of that sex will be born. It is simply the law of nature to propagate the species.

The same effect as sexual over-exertion is also produced by deficient nutrition, if the same demands are made upon the genital apparatus. Weak bulls paired with vigorous cows produced invariably male calves, while weak cows paired with vigorous bulls gave mainly birth to female calves (Tellari and Fiquet).

Next of importance is the age. At the time of the greatest sexual power, the individual of each sex never transfers his (or her) sex to that of his (or her) offspring, or does at least much less so; in most human families there are then found the most boys if the husband is much older than the wife. (Hofacker, Sadler.) It shows the intention of nature to produce more individuals of that sex which threatens to die out; the weaker, the older the propagator, the more care nature takes to have his sex propagated.

Thus far the influences concerned one sex. In case the disturbances of nutrition affect both parties the rule holds good, that where there is a superfluity of nutrition the reproduction is stronger, where a want, it is weaker. The genital system is first influenced by nutrition. (Darwin.) But it is especially the female who is more dependent upon nutrition, probably because she has to care for the bringing-up of the offspring. The logical conclusion is, that in case of superfluity of nutrition more females are born, in case of want, more males. Thus Ploss found that in the same ratio as the price of provisions advanced, the number of male children increased. (Or may not the cause be the following? It is the male that has to work hard; it is the male that suffers soonest by bad nutrition; the male, therefore, becomes soonest the weaker; therefore the result.

Laudvis procured from thousands of very young caterpillars of *vanessa urticæ*, males or females, whatever he preferred, by nourishing them either badly or well. In some of the lower animals, the females find their nourishment mainly in summer, the males in winter. In these more females are born in summer, the males in winter.

D. draws from these observations the conclusions: the sexual relation regulates itself by the property of animals and plants to produce that sex in greater numbers whose relatively greater augmentation is profitable for the propagation of the species. Even an anomalous sexual relation may benefit under special circumstances the propagation. The sexual difference may rest in the unimpregnated ovum (for instance, tendency of young ova to female sex), or the sex is determined at fecundation (young spermatozoa, males), or the nutrition (strength, age, food) decides.

Although these theories find an undeniable proof in observations and experiments made on animals (and some on human beings also), we have to be very cautious in admitting their truth. Other factors, at present unknown, probably determine, besides those mentioned, the sex of the foetus; it is even doubtful whether the latter is already definitely decided at fecundation, and whether later influences may not have their share in ordaining the sex.

DANGER FROM QUININE.

Our exchanges have considerable to say just at present about the dangers that may exist in the administration of quinine, and the injurious results that sometimes follow its use.

While it is well to utter words of caution, yet it seems almost like waste of time to caution physicians that quinine may be, in certain cases and under certain circumstances, a dangerous article; for we take it that every ordinarily well-informed medical man is thoroughly aware of this fact.

We know that quinine is one of the most valuable drugs in our possession when properly and intelligently used; and we also know that it is no exception to the rule, which holds good with all drugs, that if used when not indicated, or in a wrong way, it is capable of working harm.

If, for instance, we desire to give quinine for its tonic effects only, and we order five or ten grains thrice daily, we will do more harm than good; while, on the other hand, if we endeavor to control a well-marked intermittent fever with one or two grains, our experience will be similar to that

of the man who endeavored to extinguish a burning factory with a small syringe of water.

In a word, the indications for the use of quinine would seem to be about as follows: For intermittent and remittent fever (where we use it as a specific), we must give it in large doses an hour or two before the expected paroxysms, and in smaller doses during the intervals, until we have controlled the morbid process, or until symptoms of cinchonism supervene, when its use must be intermitted.

To reduce temperature in continued fever, it would seem best to give it in large and decided doses (10 to 20 grains) and to be guided in its repetition by the effect produced. To obtain its tonic properties, we should use it in small doses (1 or 2 grains thrice daily), and continue its use until cinchonism calls for a halt.

Thus, then, with quinine, as with opium, while valuable beyond all calculation in our warfare with disease, we must be careful to intelligently and clearly understand what we wish to accomplish from its use, else we may not only do no good, but actually do harm.

OUR SELF-SUFFICIENT EGOTISM.

It seems hard to find words sufficiently emphatic to characterize the—what shall we call it?—egotism, or blindness, or obstinacy of those who control the affairs of cities. Our outburst of indignation is caused by reflection upon the methods of supplying water to and removing refuse from our large cities.

In the matter of water supply and sewerage, our large American cities are in a condition of *barbarism*.

The experience of all time and of all peoples clearly proves to us that our methods have no elements of correctness about them; and yet, like poor, blind fools, we allow ourselves to be treated so shamefully that the condition of the wandering savage presents a sanitary elysium in comparison with our hygienically besotted condition. Can we not force ourselves to sink our egotism in the ocean of experience, and profit by the history of the world, in these two prime questions of water supply and sewerage?

THE BITE OF AN EPILEPTIC.

In England, recently, a young man was bitten in the hand by a woman who had fallen in an epileptic fit. Three days afterwards he died, and the neighborhood became greatly excited over the occurrence.

This case only tends to add additional testimony to the fact that the public love sensations.

This death may have been merely a coincidence, or again, a bite from any person or any animal will occasionally, or we should rather say, *might* occasionally, set up a degree of inflammation in an already depraved or weakened constitution, that might prove fatal.

But to suppose that the bite of an epileptic is any more serious, simply because it is inflicted by an epileptic, than would be a similar wound received from any other person, is certainly unreasonable and not to be entertained in the pathological light of to-day.

NOTES AND COMMENTS.

Exercise in the Treatment of Non-United Fractures.

These cases of non-union will oftentimes prove exceedingly annoying, hence the expedient which has proved entirely successful in the hands of Dr. G. W. Nesbitt (*Jour. Am. Med. Ass.*, January 12, 1884,) is worthy of trial.

"July 25, having first applied a close-fitting elastic stocking to the limb, as far up as six inches above the knee, I then made extension, till the fragments were brought as nearly as possible into apposition, and applied broad strips of a firm woollen blanket lengthwise of the thigh, and extending below the knee, and above the trochanter major and the tuberosity of the ischium. These strips completely surrounded the thigh, and were held in place by a roller bandage of the same material, applied firmly from the condyles of the femur to the perineum and the tuberosity of the ischium. I next applied a roller of mosquito-net, then a coat of plaster-of-Paris; and while it was yet soft, I applied strips of wire gauze, extending the whole length of the thigh, and outside of this another covering of the mosquito net, which was again coated with plaster, wire gauze, and more netting, till a splint was formed at least half an inch in thickness, and extending the entire length of the thigh. I now reflected the ends of

the longitudinal strips of blanket stuff, which was first applied to the thigh, back over the outside of the splint, and secured it by a roller bandage of the mosquito net, extending from within half an inch of the lower border of the splint to within half an inch of its upper margin, and over this applied a thin coat of plaster, which in turn was covered by a muslin roller bandage, which gave it a finished appearance and completed the dressing.

"The cushion-like margins of the splint above and below, formed by the reflection of the lining of the splint, as it were, were not only neat, but comfortable and firm, while the whole splint fitted so closely from the perineum and tuberosity of the ischium above to the condyles of the femur below as to render shortening almost impossible after the plaster became hardened.

"Extension was kept up until the splint became firmly set, when the patient was allowed to get up and go about, bearing his weight upon the broken leg without the aid of canes or crutches, except when taking a long walk—as coming down town, a distance of nearly a mile—when he used one crutch, and sometimes a cane and a crutch. But he worked about home, sawing wood and doing chores about the house, without any artificial support most of the time.

"The first few days he complained of some soreness at the point of fracture, but not sufficient to discourage him in his efforts at independent locomotion.

"He was now really self-sustaining, and I left him to take care of himself till October 6, when I removed the plaster dressing, and found that a firm bony union had taken place, with the limb in good shape, and with less than three-fourths of an inch shortening. The man has since that time been employed as a house carpenter, also in putting up wind-mills. He walks without limping, does all kinds of heavy work, and climbs a ladder with as much agility as if nothing had ever happened him."

Nasal Stenosis a Cause of Nasal Catarrh.

We have already had occasion to refer to nasal stenosis as an etiological factor in nasal catarrh, and we are pleased to see that Dr. W. J. Walsham (*Lancet*, December 29, 1883,) adds his experience to the affirmative side. He says:

"Nasal stenosis as a cause of chronic nasal catarrh does not appear to have received the attention that it undoubtedly merits, and I believe it is not unfrequently overlooked. Many of the cases of so-called intractable nasal catarrh, strum-

ous rhinitis, etc., I cannot but think depend, if not for their cause, at least for their continuance, upon some of the various forms of obstruction of the nasal cavities. During the last few years I have had under observation many such cases, and have found that after long periods of unsuccessful treatment, both local and constitutional, the symptoms have readily yielded on removing the source of obstruction.

"With regard to treatment, when the catarrh depends upon one of the forms of stenosis, it is, in my experience, useless to attempt to cure the disease without first removing the obstruction. In the case of a deflected septum this may usually be accomplished by forcible straightening, aided, if need be, by a stellar or other division of the cartilage.

"On the question of the treatment of general hypertrophy of the mucous membrane, it is not my intention to enter here. Posterior hypertrophy of the inferior turbinated bone may be removed by including the hypertrophied portion in the loop of a wire snare (that invented by Dr. Jarvis appears to answer very well), and slowly dividing the tissues included in the loop. General hypertrophy of the inferior or middle turbinated bone is best remedied by removing the whole bone, an operation attended with, as far as I have seen, neither danger nor inconvenience of any kind. The removal has been readily accomplished by means of a polypus forceps.

"Hypertrophy of the anterior end of the inferior turbinated bone may be removed by a wire snare, the parts having previously been transfixed with harelip pins. In one instance I succeeded in reducing the hypertrophy by means of frequent application of solid nitrate of silver. As a rule, however, the more radical method of procedure will, I think, be found necessary."

The Cold Douche in Maniacal Delirium.

When we remember that opiates sometimes prove very dangerous in this condition, it will be well received when we meet with safer therapeutic recommendations. Dr. Thomas Barlow (*Lancet*, January 5, 1884,) had very satisfactory results in a case of delirium tremens, from the cold douche:

"The patient was stripped, and a spongeful of cold water squeezed down his neck and back, and then freely splashed over his face and chest. It quieted him immediately. He said it was nice, and he was well pleased to have it repeated. He was then vigorously rubbed and dried, and some strong broth was given to him, which he thoroughly enjoyed. During the rubbing process he gave

one short, loose cough. The bed was soon made; there was not the slightest difficulty in getting the patient to lie down and close his eyes, and presently he dropped into a quiet sleep. We left his friends with the instruction that if he became violent again the same treatment was to be repeated, and that he was to have no physic, but only some egg and milk or broth whenever he should awake. His wife was also told by way of precaution that it was by no means infrequent in such cases (even when not treated by cold douche) to get pneumonia, and that therefore this was one of the things for which to be prepared. The patient slept quietly for four hours, then woke and was violent again. He was doused by the friends in the same way as before, and once more lay down and slept quietly. He had no delirium after this."

He subsequently had pneumonia, but recovered. Dr. B. attributes the good effects of the cold douche to nervous shock.

A Caution in Urinary Examinations.

As evidencing the necessity of great caution, and generally of more than one examination of the urine, before forming a positive opinion, the following case may be quoted from *Berlin. Klin. Woch.*:

Professor von Heusinger, in a recent session of the Aertzl. Verein in Marburg, declared that a certain individual desired to be examined in view of having his life insured. At the close of the physical examination, he was requested to urinate. As he had micturated before entering the doctor's office, he now could pass but a slight amount. The chemical examination gave a yellowish-green precipitate (saccharine). At the examiner's request, the man returned the next morning, and the urinary test presented a negative result. It turned out after a close questioning that the individual had suffered for months with gonorrhœa, and had used injections of sulphate of zinc. He had passed water and used this injection just previous to presenting himself for the first examination. Dr. Fettiën, who was then consulted, found that if a solution of sulphate of copper is added to one of sulphate of zinc and tartaric acid and caustic soda in excess, a blue fluid is formed, which contains, besides the constituents of Fehling's solution, sulphate of zinc. Added to boiling urine, the zinc is precipitated as a hydrate with a greyish-green color, and the solution turns from blue to yellow. If albumen is added, the same phenomena are observed, only the fluid above the precipitated zinc is reddish.

Pilocarpine in Scarlet Fever.

Although the majority of new drugs that are being daily offered to the profession, are very soon proven to be worthless, we occasionally receive some really valuable addition to our therapeutic resources, and among them, pilocarpine holds a high place. In the *Glasgow Med. Jour.* for January, 1884, Dr. Frank Shearer reports a case of scarlet fever, followed by coma and convulsions, treated successfully with pilocarpine, in doses of one-thirteenth of a grain, hypodermically, and he says:

"Therapeutically considered, it is very interesting to find that when venesection to a very fair amount had failed, the pilocarpine first showed its marked physiological effects, and then stopped the fits, and that after such a lapse of time as quite to put it beyond all reasonable doubt that the venesection had very little to do with the successful result. Indirectly, perhaps, it aided it, as did also the application of the hot pack, which was kept up very industriously; yet both of these methods of treatment were in operation for upwards of one hour and a half without in the least modifying the fits.

"The case is one of those which cheers the physician on his way, and bids him hope and act, however hopeless and desperate the conditions with which he has to contend may be."

Inhalations of Oxygen.

As a means of stimulating retarded tissue metamorphosis, inhalations of oxygen promise much. The *Deutsche Med. Wochensch.*, of October 10, contains the substance of a lecture given by Dr. Kirnberger in the Medical Society at Mayence, on the treatment of leukæmia and pseudo-leukæmia, in which he suggests the inhalation of oxygen as a means of obviating the retarded tissue-metamorphosis which is characteristic of this disease. He cites a case in which he employed this treatment with good results—the patient, a boy aged 10½, who had been treated with iron, arsenic, and quinine, without any benefit, improving greatly and finally becoming cured after the inhalation of oxygen, combined with arsenic internally. The boy had reached a condition of extreme weakness, being entirely confined to bed, with loss of appetite and tendency to vomiting; the spleen considerably enlarged, and the white and red blood-corpuses in the proportion of 1 to 90. The treatment began in December, 1882, and after a daily inhalation of about 30 litres, the boy could leave his bed in ten days, and could go to school about the end of February. Some variations in

his condition occurred from time to time; but about the middle of September the author considered him to be definitely cured, the number of red corpuscles having returned to the normal.

Treatment of Varicose Veins.

This neat and simple operation is described in a contemporary by Mr. Folker, who has found it very satisfactory. A small incision was made on each side of the vein; and a curved needle, passing in at one incision and out at the other, carried the ligature under the vein, and was withdrawn. A flat instrument was now, in the same manner, passed in at one and out at the other incision, and threaded with one end of the ligature, which then, by its withdrawal, passed the ligature over the vein. The two ends of the ligature, which now surrounded the vein, projected through one opening. This was repeated in as many places as might require it, and then the lowest one was tied first, and the ligature cut off close; firm pressure was made over it just to press out any drop of blood that might be present, and the little opening was closed with collodion. Each ligature, from below upwards, was tied in a similar way, pressing the blood out of the vein up to each ligature before tying it. The ligature used in the present case was pure silk, well carbolized; but Mr. Folker hoped to tie some with tendon-ligatures, which would become thoroughly absorbed sooner than the silk.

More About Jequirity.

Dr. Hotz thus sums up his experience of 65 cases in the *Chicago Med. Jour. and Ex.*, February 1884:

1. Jequirity is the best known remedy for chronic granular conjunctivitis.

2. It is the most effective remedy for the clearing of trachomatous pannus, and in inveterate forms of pannus it is preferable to peritomy, as well as to the inoculation of blenorrhœal virus, because it does its work quicker than the operation, and safer than the inoculation.

3. It has no injurious effect upon the eye, and can be used with perfect safety even when the cornea is ulcerated.

4. But it should not be used while the cornea and conjunctiva are acutely inflamed.

5. It does not benefit those cases of chronic conjunctivitis in which the symptoms of catarrh (increased secretion, succulence of the retro-tarsal folds, etc.,) predominate over those of trachoma (enlarged papillæ, and lymph follicles, plastic infiltration of tarsal conjunctiva).

6. The most violent attacks of jequirity ophthalmia accomplish the speediest cures of granulated eyelids, and the quickest clearing up of the vascular cornea.

Unsuspected Albuminuria.

We have taken occasion recently to refer to this subject, and our remarks receive additional import from the following case reported by Dr. McKew in the *Maryland Med. Jour.*, January 12, 1884:

A boy, æt. 15, presented himself suffering with severe headache; he was otherwise apparently perfectly well. Examination of the urine revealed exceedingly delicate traces of albumen, amounting to merely a slight opalescence. The microscope revealed casts. A cautious opinion was given. The disease has advanced rapidly, until now the patient is dying of bronchial effusion. There is no assignable cause for the albuminuria in this case. At 3 the patient had scarlet fever, and one and a half years ago he had typhoid fever. He has had nystagmus for some years. The urine now contains fifty per cent. of albumen. The case teaches the importance of examining the urine whenever the cause of disease cannot elsewhere be found.

Conservative Treatment of Compound Fractures.

By resection of the injured ends of the bones and wiring together of the fragments very good results have been obtained in cases where amputation would have been formerly considered to be indicated. For instance, in the *Brit. Med. Jour.*, January 5, 1884, Mr. Wright relates a case of resection of the humerus and wiring in a recent compound fracture. There was a large lacerated wound nearly severing the arm, but leaving the skin, vessels, and nerves on the inner side intact. The periosteum was torn off a part of the humerus, the forearm was also fractured. The base-ends of the humerus were removed, and two silver sutures inserted. Good union and a nearly perfect limb resulted.

Eucalyptus in Pulmonary Gangrene.

Extreme fœtidity of breath, cough, dyspnoea, and fever, with dullness in a definite location, tubular respiration and crepitant râles, and black and very offensive sputa, caused Dr. Bonamy (*Le Courier Med.*,) to diagnose pulmonary gangrene. The patient was first put upon a mixture containing carbolic acid, but no improvement following, this was replaced by tincture of eucalyptus. In

two days after the last prescription, the odor of the breath was much less offensive, and in less than two weeks the patient was cured.

Death from Gluttony.

Two cases are reported in an exchange. The first is that of a railway clerk, who appeared well when he went to bed on Christmas night, but died before morning. The medical man who examined the body found the stomach largely distended with undigested food, which had stopped the action of the heart. The other case was that of a negro from Sierra Leone, in whose stomach whole potatoes were found.

CORRESPONDENCE.

Duty of Professional Secrecy.

EDS. MED. AND SURG. REPORTER:—

I take the following extract from my note book: "March 21, 1882. This afternoon a man came into my office, and, after asking me if I were a surgeon and for a private interview, told me that he wanted to get three bullets extracted, one from his arm, one from his leg, and one from his back."

The manner and conversation of this man left no reasonable doubt in my mind that he was a rogue trying to escape from the penalty of violated law. He left my office, and I heard no more of him from that day to this.

I give these few points in the above case in order to ask my professional brethren what is the duty of a physician in this case, or such cases, to the public. Is the physician under obligation of secrecy to his patient, or is he under obligation to the public to catch, or help catch, the rogue? How far will his obligation of secrecy protect him from being charged with being a party to the crime? Will a patient's non-payment of fees release a physician from his obligation of secrecy?

H. NYE, M. D.

Enon Valley, Pa., Feb. 11, 1884.

[1] We would suggest that the non-payment of a fee does not release the physician. Two wrongs do not make one right. (2) His obligations to society are such that a physician should render all the aid possible in bringing a criminal to justice, but he should not act on mere suspicion. He should have ample and solid grounds for action before his professional obligations to secrecy are excused.—EDS. REPORTER.]

The Ethics of Consultations.

EDS. MED. AND SURG. REPORTER:—

So much has been said within the last two years in regard to ethics and consultations that it would seem that all the points in controversy ought to have been settled; but nothing that I have read covers the case I have in view, and what I state is with the object to receive information.

To illustrate my point: Last summer, in a conversation with Prof. R——, of Hamilton, Ohio, he said: "I would like to meet my competitor,

Prof. W—— (who is a homœopath) in consultation; he is a worthy gentleman and a skillful physician; but it would not be consistent in me as a teacher in the regular school, and as a member of the medical societies representing progressive medicine."

I thought to myself, Prof. R—— has a higher aim than the consideration of dollars and cents.

Now the opposite of Prof. R—— is Dr. V——, of this county, who is regarded as the leading surgeon of this section, and a member of the State Medical Society, who counsels with a "physio-medical" doctor upon all occasions. The physio-medical *genus* is a rare specimen of the *genus homo*, and perhaps you do not know him by personal contact in the East, as he is *indigenous* to the country west of the Ohio river.

Now, how can a doctor be a member of the "State Medical Society" and consult with a doctor of the above class? Information respectfully solicited.

B. P. ZELLER, M. D.

Brock, Ohio, January 2, 1884.

[We confess to some uncertainty as to what a "physio-medical doctor" may be, but we do acknowledge to a clear conviction that neither the profession nor the public can gain by consultations with men who practice medicine under the avowed influence of prejudice and dogma, who reject well-established means of diagnosis, who deny the utility of pathology, and who discard well-tried remedies merely because they are "mineral" or "poisonous." It is a mere sham to pretend to consult with such men.—EDS. REPORTER.]

A Criticism Corrected.

EDS. MED. AND SURG. REPORTER:—

I have no desire to enter into a controversy with Dr. Guild concerning the case reported by me for your magazine some weeks ago. His communication, however, contains so much that is unfair and *misapropos* that I cannot, in justice to the gentleman who attended Dr. A., or myself, allow the criticism to go unquestioned.

Dr. G. has evidently been laboring under the impression that I attended the case; this is a mistake, as a more careful reading of the article would have shown. I state distinctly that "I am indebted to the attending physician, Dr. J. J. Ward, for the notes," and so far as the death certificate was concerned, instead of "demurring," as Dr. G. says he did, he made it out "apoplexy" himself. Whether this was correct or not, I am sure I cannot say, but it seems to me, that to have headed the article "A Case of Possible Apoplectic Coma" would have been just as nearly incorrect—if I was incorrect—as the other. I have never known before that "errors in diagnosis" could be committed where no diagnosis was made. There certainly was no conclusion arrived at in the article. The word "possible" is used in the heading. In one place I say, "a satisfactory diagnosis was not made;" in another, "we confess that the complexus of symptoms here present puzzle us," and finally, that "we are inclined toward the diagnosis of death from heart failure, caused by chloric ether." I submit, that though here and throughout the whole article there is plenty of room for difference of opinion, yet I can hardly be accused

of "errors in diagnosis." Why the allusion to "heart failure" was made is briefly this: Chloroform by the mouth produces, according to Bartholow, "stupor and insensibility," it also increases the "action of the arterial system." Now, if "over stimulation produces exhaustion," why is it so extremely unreasonable to suppose that the poison produced the coma and other symptoms referable to the nervous system, and that when he had partially recovered from its effects, sudden exertion, sitting up in bed, vomiting, etc., produced failure of an organ not as strong as it once was and now weakened still more by over-stimulation? Far be it from me to aver with any degree of certainty that such was the case. I have learned, however, to be very cautious about using the word "never" in matters pertaining to medicine.

In regard to therapeutics, I have but to say that when Dr. Guild will point out the passage wherein it is stated that alcoholics were administered, I will discuss with him the advisability of so doing. It is indeed stated that stimulants were "pushed," and so indeed they were, as much as it was possible under the circumstances; but the "stimulants" were carbonate of ammonia and digitalis. It is of course not to be supposed that Dr. Guild knew this, but he certainly knew that there were other stimulants beside alcoholics, and that no mention of the latter is made in the article which he criticised. And I may here say that not only in this connection has he misrepresented me, but he does likewise in his brief epitome of the case at the beginning of his article. Any physician who will take the trouble to read my communication carefully, cannot fail to be impressed with these two facts, and such will see the injustice of Dr. G.'s arraignment.

I close here by expressing the hope that any physician who has had opportunities for examining any cases such as the late Dr. A.'s was, will publish his conclusions. S. M. WARD, M. D.

Ellenville, N. Y.

Metrical Anatomy of the Eyes and Orbits.

EDS. MED. AND SURG. REPORTER :—

The depth of the orbits from the supra-orbital foramen to the optic foramen is 5 centimeters, and the lateral diameters at base 4 centimeters. The supra-orbital foramen is 4 centimeters from the outer part of the sphenoid fissure, and from the margin of the orbits (externally) to the nearest point of the sphenoid fissure is 32 mm., this being the nearest distance to the brain. From margin of orbits (at lachrymal canal) to the optical foramen is 45 mm. From outer and lower margin of the orbits to the nearest point of sphenomaxillary fissure is 15 to 18 mm. 4 or 5 mm. below the margin of the orbits is the infra-orbital foramen. The depth of this canal is 17 mm. The anterior ethmoid foramen is 33 mm., and the post ethmoid foramen 39 mm., within the margin of the orbits, measuring from the lachrymal canal. The lachrymal canal is 2 to 3 mm. within margin of the orbits, and is 4 mm. in diameter. The nasal duct "is $\frac{3}{4}$ inch" in length. The diameter of the optic foramen is 3 to 4 mm. About 3 mm. "external to the lachrymal canal at inner and forepart of orbital surface of maxillary bone is the depression for attachment of inferior, oblique, and lachrymal tubercle." The tendo oculi two lines in length and

one in breadth, is attached to the maxillary bone 5 mm. above the lachrymal canal. The pulley of superior oblique is 13 mm. above the lachrymal canal; arising "about a line above the inner margin of the optic foramen," it is inserted into the sclerotic midway between the cornea and entrance of the optic nerve. The tensor tarsi is 3 lines in breadth and 6 in length. The recti muscles are inserted into the sclerotic, 3 lines from the margin of the cornea. The diameter of the pupil varies from 1 to 8 mm., according to its dilatation or contraction.

* * * * *

A knowledge of the depth and metric relations of the orbits is useful to the surgeon in performance of the operation of enucleation of the eyeball, and probing, etc. No instrument should be introduced beyond 32 mm. from the outer margin of the orbits, nor in no case should they go beyond 45 mm. The lachrymal tubercle serves as a guide to the surgeon in the operation for fistula lachrymalis—a knowledge of the size of this canal is useful in applying instruments to it. If a vertical line is drawn across the base of the orbit, the degree of divergence or convergence of the pupil can be metrically expressed.

Pleasant Ridge, Ala.

NEWS AND MISCELLANY.

Ohio State Sanitary Association.

The first annual convention of the Ohio State Sanitary Association met at Columbus on the morning of the 14th inst. Dr. William M. Beach, of London, was unanimously elected temporary chairman, and accepted with a short speech. The high waters detained many, but before evening adjournment the room was comfortably filled with physicians and scientific men from all over the State.

Rev. Dr. W. E. Moore of Second Presbyterian Church prayed, and Dr. R. Harvey Reed, of Mansfield, was chosen temporary secretary.

Dr. C. M. Finch, President of the Board of Education of Portsmouth, who was to plead for a State Board of Health, was not present—probably detained by the floods.

In accordance with arrangements, Dr. Baldwin delivered an address of welcome, in which he referred to the sad effects of the sewerage system of this State upon the public health, and set forth a number of important topics which he deemed of importance, and which he thought should receive the attention of the student of sanitary science.

The response to Dr. Baldwin's address was made by Mr. John Simpson, Ph. D., superintendent of the Mansfield public schools. He advocated a more thorough and general education in sanitary science, believing that a more wide-spread knowledge of hygiene would have a wholesome effect on the public health, and would prevent many of the common abuses. "Were a sound body the rule instead of the exception," he said, "the condition of the race would be materially improved in this age of stupendous progress."

The Chair, at the close of the address, ap-

pointed the following committee on permanent organization: Drs. J. F. Baldwin, Columbus; X. C. Scott, Cleveland; E. H. Hyatt, Delaware; G. S. Franklin, Chillicothe; C. A. Lee Reed, Hamilton.

Dr. Beach, of London, the temporary chairman, read an interesting paper on the "Importance of Sanitation." The production displayed a very intimate acquaintance with the history of sanitary science. It reviewed at considerable length the history of the plagues that swept over Europe during the middle ages, giving a general idea of their severity, and some of the mediums by which pestilence is spread. Dr. Beach is not in favor of fumigating bedding and other clothes after the poison of pestilence has once been retained in them, but thinks that the physician should enforce positive sanitary precautions by having the articles burned. The history of the custom of quarantining against the epidemics of cholera and yellow fever was run over, and the doctor expressed himself as in favor of it. The paper closed with an eloquent peroration.

A letter was read from Dr. James E. Reeves, of Wheeling, secretary of the West Virginia Board of Health, who was expected to address the present convention, cancelling the engagement, as he was needed at home to help take care of the people rendered destitute by the flood.

Dr. G. S. Franklin, of Chillicothe, read a voluntary paper on the effect of slaughter-houses upon public health, in which he expressed himself as in favor of placing the control of all such institutions in the hands of boards of health.

The association then adjourned until 2.30 p. m.

The first thing on the programme for the afternoon was a paper on "Drainage and Water Supply," by Professor E. H. Hyatt, M. D., of Delaware. Dr. Hyatt, however, said that he would willingly give his time to the discussion of the Scott bill, and the Society accepted the offer. Dr. Scott, of Cleveland, the champion of the bill, then took the floor and explained what the bill was intended to do.

The Association spent the greater part of the afternoon discussing this Board of Health bill, the following gentlemen participating in the discussion: Professor E. H. Hyatt, of Delaware; Dr. Conklin, of Dayton; Dr. McCurdy, of Mahoning county; Dr. Reed, of Hamilton; Dr. Baldwin, of Columbus; Dr. Silver, of Sidney; Dr. Reed, of Mansfield; Dr. Beardsley, of Ottawa; Dr. Beckwith, of Cleveland; Dr. H. J. Sharpe, of London, and Dr. Franklin, of Chillicothe. All who spoke were strongly in favor of the tenor of the bill, and nothing more than suggestions as to how it might be improved were made. The question was raised whether it would not be better to create two boards, a board of examination and a board of health, instead of vesting the two powers in one body, as the bill contemplates. Dr. Baldwin thought one board would be sufficient. Too many boards was not a thing to be desired. Dr. Reed, of Mansfield, brought up the question of signing the certificates. He wished to know if the certificates of new-school men would only be signed by the new-school members of the board. There was considerable talk over this subject, and the matter was finally settled by Dr. Scott stating that it was the intention of the bill to require the signatures of the President and Secretary of the Board to the certificates.

The following committee was appointed to confer last evening in regard to the proposed amendments: Dr. Scott, Dr. W. J. Conklin, of Dayton; Dr. Beckwith, of Cleveland; Dr. Beardsley, of Ottawa; Dr. Baldwin, of Columbus; Dr. Beach, of London; Dr. Franklin, of Chillicothe; Dr. Jones, of London; and James Alison, of Cincinnati.

The regular programme was then taken up, and Dr. John McCurdy, of Youngstown, read a paper on "Sewerage and Water Supply of Youngstown." The Youngstown people use the Holly water system and main trunk sewers.

Mr. James Alison, a delegate from the Master Plumbers' Association of Cincinnati, read a voluntary paper on "The Plumber in his Relation to Sanitary Progress, as Viewed from the College of Practice." The paper was one of the best of the meeting.

Professor Hyatt's paper on "Drainage and Water Supply," and Professor Conklin's paper on "Sanitation in Schools," will be read this morning.

The convention, after hearing Mr. Alison's paper, adjourned until evening.

The evening session was held in the House of Representatives, commencing at eight o'clock. There were about one hundred persons present, among them being a number of members of the General Assembly.

Dr. Beach took occasion to return thanks for use of the hall, and called for the first paper of the evening, the opening by Dr. Starling Loving of discussion on the resolution, "That Legalized State Sanitation has Become a Necessity in the State of Ohio, for the General Protection of Its Citizens." He held that thousands of deaths occur annually in Ohio from preventable diseases, and referred to the Secretary of State's report to substantiate his statements. These deaths, he argued, were a direct loss of many millions of dollars to the State, and some legislative action should be taken to prevent them. He favored the appointment of a board of competent physicians to examine all medical college students; and also a State board to take charge of sanitary affairs.

Discussion of Dr. Loving's paper was opened, and Dr. John McCurdy, of Youngstown, and Dr. Reed, of Mansfield, took part.

Professor W. J. Conklin read a paper on the "Influence of Public Schools on Brain-building," which did not elicit discussion, from the fact that his statements coincided with the views of most members present.

The convention then adjourned till next morning.

At the morning session, the first order of business was the report of the committee on permanent organization, who reported the following:

President—Wm. Morrow Beach, M. D., London, O.

First Vice-President—Prof. Edward Orton, Columbus.

Second Vice-President—Professor Nelson, Delaware, O.

Third Vice-President—Hon. L. D. Brown, Hamilton, O.

Secretary—R. Harvey Reed, M. D., Mansfield, O.

Treasurer—Prof. John Simpson, Mansfield.

Executive Committee—Prof. Starling Loving, M. D., Columbus; H. D. Beckwith, M. D., Cleveland; W. J. Conklin, M. D., Dayton; E. H. Hyatt, M. D., Delaware.

Committee on Admissions—C. E. Beardsley, M. D., Ottawa; John McCurdy, M. D., Youngstown; and D. R. Silver, M. D., Sidney.

Committee on Publication—Drs. R. H. Reed, J. T. Baldwin, and Geo. A. Collamore.

Committee on Legislation—Drs. Wm. M. Beach (*ex officio*); X. C. Scott, Cleveland; C. S. Van Pelt, Toledo; T. C. Minor, Cincinnati; J. R. Flowers, Columbus; and C. M. Finch, Portsmouth.

The report was adopted.

The committee on constitution also made a report. They had prepared a constitution, which was read and adopted. The name of the organization is to be the Ohio State Sanitary Association, and the object of the Association is the general advancement of sanitary science, and the encouragement and promotion of local organizations throughout the State. The membership will be of two kinds, active and honorary. Active members shall form the body of the association, and shall be selected with special reference to their interest in sanitary studies and allied sciences. Honorary members shall be selected with reference to their general interest only in the work in hand. The association will meet at least once a year, in the month of February, and unless some other city is mentioned, will meet in Columbus.

Professor Curtis C. Howard, Professor of Chemistry in the Starling Medical College, read a paper on Impurities and Adulterations of Milk, the result of a series of examinations of the milk of the Columbus market. The professor thought there was little adulteration in the way people generally suppose. As for chalk, it is insoluble, and if mixed in clear water, it will be turbid for a time, but after standing a while all the chalk will settle and the water will be clear again; so, also, with brain matter, which some claim to have found in milk. It could not be put in without spoiling the whole of the milk. Water, however, may be added *ad infinitum*, and the quality of the milk will be in inverse proportion to the amount of water used. The professor exhibited a chart, which showed the results of his work.

The next paper was read by Dr. D. N. Kinsman, of Columbus, on "Some Reasons for the Establishment of a Board of Health." He called attention to the amount of disease arising out of ignorance of the causes of disease. Every section of country has its particular industry, and each industry has its own peculiar diseases. How to prevent them should be the work of the Board. He referred to the importance of obtaining accurate vitality statistics, and thought a good Board could do this work in a way not done as yet.

Dr. S. H. Smith, of Warren, who was on the programme for a paper on "Diphtheria," and Dr. J. W. Craig, of Mansfield, for a paper on "Tobacco from a Sanitary Point of View," were absent.

On motion, a paper on "The New Fashion," by Dr. C. A. Lee Reed, of Hamilton, was read. It referred to the absence of athletic sports among the people in general, and hailed what seems to be the approach of an era when the pell-mell, hurry-skurry of American business life, will be

broken into a fair amount of refreshment and rest.

Dr. Lew Shusser, of Canton, read an essay on "Vital Statistics," a paper illustrating the great need of correct vitality statistics.

The remaining part of the morning session was taken by Dr. Beckwith, of Cleveland, who read a paper on "Sewers and Sewer Gas."

Adjourned till afternoon.

At the afternoon session, F. H. Darby, of Morrow, who was on the programme to read a paper, not being present, and sending his regrets along with his manuscript, the paper was read by the Secretary. The subject of the essay was "Blood Poisoning."

The only other paper on the programme, that of Prof. Edward Orton on "What shall be done with our Sewage and Garbage," was, at the urgent request of the writer, who had been prevented by illness from completing his paper, held over until next year. The professor made some very befitting general remarks, however, on the general subject of sanitation.

After a short and enthusiastic address by the President, Dr. Beach, the Association adjourned to meet in Columbus next February.

WM. MORROW BEACH, M. D., *Pres.*,
London, O.

R. HARVEY REED, M. D., *Sec'y.*,
Mansfield, O.

Correction.

Dr. Hiram Corson writes us: "On page 15 of the pamphlet containing 'Proceedings of the Alumni Society of the Medical Department of the University of Pennsylvania,' there is an error which I should like to have corrected through your REPORTER. The cost of Morris Plains Hospital is there given as \$800,000, instead of \$2,800,000, as it should be."

OBITUARY NOTICES.

D. L. ALLEN, M. D.,

Of Shenandoah, Iowa, died at Princeton, Kansas, of consumption, January 24, 1884, aged 36 years, 8 months, and 6 days.

Dr. Allen graduated in the class of '74 at Long Island Medical College. He commenced the practice of medicine the same year at Academia, Pa.; continued there till the fall of '81, when his rapidly failing health warned him to seek another climate, when he located in Iowa, and for a short time seemed to improve, till another attack of pneumonia left his lungs so much weakened that he never regained his strength. Change of climate and medicine made no change in him.

He was a physician of rare judgment, and a surgeon of accurate skill, a friend to the poor, and a Christian gentleman. He leaves a wife and one child.

DR. FRANK O. NAGLE.

Dr. Frank O. Nagle died at his residence, No. 2004 Germantown avenue, this city, February 1, in his twenty-seventh year, from a complication of diseases, resulting from typhoid fever. At the time of his death he was Professor of Therapeutics and Materia Medica in the Medico-Chirurgical College. Dr. Nagle graduated at the University

of Pennsylvania in 1879 with honor, receiving the Hodge gold medal, and afterwards was on the medical staff of the Philadelphia Hospital. He was a member of the County Medical Society and Philadelphia Chemical Association, and contributed several articles to this journal.

Items.

—Alcohol will be found effectual in removing ice from show-windows.

—Prof. Bartholow says that thymol is the best agent to destroy the odor of iodoform.

—Prof. Da Costa recommends chloral hydrate, in three-grain doses *ter die*, for infantile incontinence of urine.

—Professor Virchow has come out in favor of American pork. He declares that there is no danger in it, and that the shutting it out from Germany is a political, not a sanitary measure.

—Artificial oysters are supplied to the Paris markets, according to a *feuilletoniste* of the "Union Médicale." They are colored by means of copper, and are cemented to the interior of old shells.

—Fenoglio recommends the injection of ergot in cases of splenic enlargement due to malaria. He recommends Bonjean's ergotin, dissolved in hot water, injected before the midday meal, while the stomach is empty.

—Dr. S. W. Gross recently performed the first stage of the operation of gastrostomy on a woman aged fifty-one, suffering from carcinoma of the œsophagus. On the eighth day the woman's temperature and pulse were normal, and the case was progressing most favorably.

—The Secretary of the Treasury has approved the recommendation of Surgeon General Hamilton, that an immediate inspection be made of the cities bordering on the Gulf of Mexico and the Caribbean Sea, having commerce with the United States, in order that their actual sanitary condition may be known in advance of the yellow fever season.

—The London *Saturday Review*, in an article on "the silly and ignorant agitation against vaccination," says, justly, that "people who do not choose to have vaccination performed on themselves or their children are as much guilty of spreading disease as if they turned poisonous matter into a reservoir of drinking water, and deserve no more quarter."

—A libel suit having been brought by a member of the medical faculty of the University of Michigan against a newspaper that had charged him with criminal relations with a lady who was his patient, \$20,000 damages were awarded by the jury, and, the case having been appealed, the Supreme Court has affirmed the judgment.

QUERIES AND REPLIES.

Gynæcological Queries.

EDS. MED. AND SURG. REP.—

1. Will some reader kindly give me some hints for treatment of the following case: Multipara, aged twenty-six years, for some years past has had almost complete menstrual suppression. Periods occur but once or twice a year. Is subject to sick headache and backache; is anæmic, and

has very little appetite; more or less leucorrhœa. Examination per speculum reveals a slightly enlarged uterus and cervix, also a slight degree of retroversion. The os presents the so-called ulcerations. She has been treated by all the physicians in her vicinity, and has taken every form of emmenagogue and tonic without the slightest benefit. Her only living child is five years old, and since his birth her trouble is greatly aggravated, though it has existed to some degree for eight years. Prior to that time, she menstruated normally; but on one occasion, in attempting to hold in a team of runaway horses, she so strained herself that a very alarming uterine hemorrhage resulted. From that event dates her trouble. Marriage and pregnancy produced no change.

If any of your readers can suggest a course of treatment liable to result in benefit, I shall be very grateful.

2. I would be glad to receive information as to some method of applying astringent remedies to the vagina without using injections. My patients so frequently complain of the latter mode of treatment as being so inconvenient, painful, or consuming so much time, that I am constrained to seek some form of medication more easily applied.

MEDICA.

Use of Alcohol.

EDS. MED. AND SURG. REP.—

I have received a number of answers to my request on "Alcohol, Its Use and Abuse as a Medicine," published in the MEDICAL AND SURGICAL REPORTER, issue of February 2, 1884, page 159. I would like to have a much larger expression of the views of the profession on this subject, and therefore ask every one who reads this to be kind enough to briefly state their views and send them to me at their earliest convenience. Don't wait for some one else, thinking your views are not wanted, but send me your views, as I am very anxious to have them. Fraternally,

JOHN B. CARRELL.

Fowler's Solution.

Query.—Does Fowler's solution of arsenic deteriorate by age? Does it ever become worthless by long keeping? If it loses its strength by age, what is the chemical process of its so doing? Yours truly, D. N. P.

Mangum, N. C.

We have referred this query to one of our ablest chemical pharmacists, who replies as follows:

"Fowler's solution, with ordinary care, cannot become worthless by long keeping, and it is a question whether the article deteriorates from any such cause. If, however, a change should take place, it would be owing to the alteration of the arsenite (so-called) into arseniate of potassa. The dose and therapeutic value of the latter would be about the same as the former. If any deposit should occur, it would be probably the coloring matter from the compound tincture of lavender contained in the preparation.

"In pharmaceutical preparations of this kind, it is not well, however, to keep them on hand too long.

"Injurious or not, the long keeping of them puts the dispenser, to say the least, in an uncomfortable position. I usually prepare Fowler's solution in about one-half pint quantities, which will be used in about three or four weeks. This insures a fresh preparation, and me more satisfaction, though I may know the preparation would be equally as good if a year or more old. I am yours,

"L. E. SAYRE, PH. D."

Dr. J. R. asks: Can a graduate of a standard medical college practice in the State of Illinois without an examination?

Ans.—Yes.

MILK, GOOD AND BAD.

BY SAMUEL PETERS, M. D.,
Cohoes, N. Y.

The agitation that has been going on for years past in our large cities in reference to this subject has resulted in a full decision of the fact that there is good milk and bad milk; that good milk is sadly the exception in cities of any size, and bad milk the rule; that good milk is nature's own perfect combination of all the nutrient principles required for our nourishment, and suitable for all ages and almost all conditions, whereas bad milk is deleterious to persons of any age, especially and particularly to tender infants and young children, causing and keeping up such an indigestion and stomach disease as to produce our most dreaded diseases, such as cholera infantum, diarrhoea, dysentery, marasmus, fevers, restlessness, etc. So constantly has this been demonstrated and proved over and over to be the truth, that careful physicians are always afraid of it in the cities, whereas they are hearty and free in recommending it in the country. In the latter place, where it is pure, they find it not only admissible, but absolutely desirable, in any case where the body needs active support; and in infants where the natural food, the mother's milk, is unhealthy, insufficient in quantity, or altogether wanting, infants are feeble and pale in the cities as a general rule, plump and hale in the country. A large percentage die in the cities; a very small proportion in the country. In the places where the milk has been rendered impure

and unfit for use, the physician finds his remedies only partially successful, where they should and would be speedily so, owing to the fact that the principal, or certainly one of the active causes remains, namely, improper food. One hundred often die in a single day in New York city, fed as they are on inferior milk, whereas probably not ten per cent. of that number would succumb if furnished the pure, natural, delicious milk as one article of their food.

Hence, in infants artificially fed, the habit of physicians in our larger cities is to send at once their little patients, affected with cholera infantum for instance, directly into the country, alleging, as the principal reason, the benefit to be derived from the pure air—whereas, as they may or may not know to the full extent, the efficient cause of the expected improvement is the improved, or rather the perfected diet the infant is to receive. This, surely, is a commendable fashion, and has been the means of saving thousands of precious little lives, and in the writer's opinion, a fashion that cannot become too general.

The causes of bad milk in the cities are various. They may be studied with a fair degree of certainty, but probably they can never be removed. Their nature is such that avarice and deceit can and will maintain the ascendancy.

The object of this paper is not so much to enumerate all the causes that contribute to the production of bad milk as it is to speak of the direct and decided injury that milk receives from the bad feeding of our dairies.

Because a cow will eat almost anything when it is hungry, is not proof that such food is always proper. I need not here refer to the long-estab-

lished fact that the character of the food gives character to the milk. For instance, mothers are well aware that indulgence in certain articles of diet affects her nursing child; therefore, she is careful in avoiding improper food. Physicians often prescribe remedies for the infant by giving them to the mother. Pavy mentions the fact that saffron and madder given to cows or other animals, colors the lacteal secretion; that cabbage and onions impart odor to this fluid; that bitter articles render it bitter, etc. The same authority informs us that both meat and milk may be poisoned by certain articles of food, without the animal itself being poisoned or even sensibly affected. Cows as well as human mothers may continue to secrete colostrum for a long period—of course an entirely improper food for persons of all ages. Infants may be purged or even salivated through the mother. Colds, and even fevers, are supposed to be taken from the mother.

Grass-fed cows, kept in warm, well-ventilated quarters, if healthy themselves, afford healthy milk, unless for some unknown reason colostrum continue to be unduly secreted. I know a marked instance of this: A family in the country kept two cows, both young and healthy; the milk of each was apparently identical. A child of the family was given for its ordinary diet the milk from one of these cows. When the child's mother wished to administer a cathartic to her infant, she gave it the milk from the other cow, and it was always sufficient. Now, suppose the mother had persisted in trying to rear this child on the milk of this second cow, the result can be readily anticipated. Clinical experience is worth more than all the theories that can be advanced. We may not always be able to point to the identical article that acts as the primary cause in inducing a child's discomfort or disease, yet such clinical experience may finally lead to beneficial results. A child begins, for instance, to decline in health; nutrition is evidently imperfect; its color is changed; its evacuations have an abnormal appearance; it is restless night and day. Send it away into the country, and rapidly it begins to improve; the mother or nurse neglects the doctor's medicine, the child is well. Now, what other process of reasoning can appear so plausible as that the diet has improved and cured the child? It is true, air is an important pabulum, but it surely is no more important than food; and here again clinical experience teaches us that perfected diet cures probably more cases than perfected air; one of these remaining unchanged. I say *more*, perhaps, in fairness, this expression should be

modified so that both appear equal. Each needs its share of attention; each must be jealously watched. Hence the conclusion is fairly this: bad milk is one of the serious evils, and is to be found almost exclusively in the cities, where milk is supplied by pedlars from the larger dairies, the managers of which make it a business for the very purpose of realizing the largest returns possible.

In such cases it is natural to strain every possible point that promises the largest profit. The dairies are kept at the smallest possible expense. The cows are huddled together in narrow, filthy apartments, often given the coarsest and cheapest of grass or hay; food that cannot be economized for any other purpose; dirty, coarse, half-spoiled clover, refuse material and slops from the house, rancid dish-water often, and refuse vegetables in a fermenting state; grains from sunken boats, that are sour and undergoing the putrefactive process; potatoes that are half rotten, and other damaged and worthless vegetables.

By such a process, a small farm often supports a large dairy; the number of acres, perhaps, less than half the number of cows. The country is ransacked for cheap feed; sugar-houses and breweries are besieged for every pound of refuse that can be produced—this refuse often, and indeed generally, in an advanced state of decomposition, if not soon becoming so—all fed as carefully as possible, and so long as its putridity does not prevent the poor cows from eating it. The small balance, if any, is then thrown away, with many regrets that animals would not gobble down the whole, good or bad. Such is too often the fountain that supplies our milk, and such is the description of facts that must obtain to a greater or less extent everywhere—that is, where dairy farming is made a business.

Milk we must have, and we must digest it as well as we can. Adults generally in health can accomplish the task, but out of health, it too commonly becomes a problem. The curd becomes hard and indigestible, especially in the stomach of a person, for instance, whose temperature during a typhoid fever stands at 103° or more; whereas, the curd of healthy, pure milk should be soft, porous, and easily digested.

Here comes the "tug of war." The patient must have active support to enable him to tide over the fever period; he must have concentrated food—food that contains all the requisites of the animal body, and as nearly as possible in their proper proportions. And we well know, pure milk is all this; all that we can ask for; nature's own food,

and, of course, perfect; a food that can hardly be substituted. Then to find our patient becoming restless, his temperature rising, having, perhaps, evacuations of undigested curd, or, more likely, no evacuations at all; bowels tender, with slight colicky pains—we cannot but make the resolve that, at any risk, we must discard the milk; and we cannot but harbor a hearty wish, further, that we could secure the pure, rich, perfect milk from the country.

After all, such a condition of things is nothing to that of a child that is to be artificially reared or largely fed on milk, especially such milk as is too often distributed to city consumers. Here not only the health, but the very existence of the child is in jeopardy. The little one dwindles, becomes diseased, drugs are carefully and skilfully administered, but fail; and the patient dies, virtually from the effects of a slow and insidious poison, namely, bad milk.

The various forms of improper dairying have been spoken of, and it remains only to allude to one which seems to me to be the most common and the most dangerous of all, viz., the feeding of sour or fermenting articles of whatever form or nature, either slops from the kitchen, wet grain, refuse grain, and other material from breweries and sugar-houses, or glucose factories; any and all of these, if in a fermenting state.

These, if fed in any but a very limited amount, deteriorate the quality of milk, and should be absolutely discarded by all dairymen. The happy day when they decide to do this will be undoubtedly long in coming, but as sure as intelligence increases among the masses to a proper extent, so sure is the day to dawn.

The importance of this question has not escaped the attention of our State Board of Health. See second annual Report, page 503; also page 704. I have in my possession an autograph letter from the Secretary of this Board, Dr. Elisha Harris, which refers to the point in question, an extract of which I here give. He says, "Concerning the wet and sour feed for milch cows, I can add nothing to what I wrote you some months ago. The cows become sickly and die in the course of two or three years. Their milk, at first redundant in butter, becomes disordered as organic disease and asthenia supervene."

"This Board now has four inspectors devoted exclusively to inspection and protection of milk supplies, and we hope that useful results may be attained."

It should be here stated that these refuse grains from brewing and glucose houses are not so inju-

rious if rapidly and perfectly dried, so that fermentation is perfectly and permanently arrested. This, however, I apprehend, is rarely accomplished, the fermenting process recurring after a number of days, because not fully arrested.

CHRONIC NASAL CATARRH IN CHILDREN.

BY HARRISON ALLEN, M. D.

Professor of Physiology in the University of Pennsylvania.

(Continued from page 231.)

Frequency and Diagnosis.—From a somewhat extended experience in the treatment of these and allied disorders, the writer has concluded that chronic nasal catarrh in the child is a rare disease, and must be separated from the catarrhs which are so common with the children in this community. A child otherwise healthy, who contracts a severe cold, may have a duration of the nasal discharge for a time, which excites the apprehension of the parents, and the advice of the physician is asked. If no other sign exists but the discharge, that is to say, if the characters already enumerated are absent, the case can be diagnosed, *subacute nasal catarrh*. If, however, in connection with the discharge, distinct evidences of malnutrition exist—as instanced in the skeleton—in the tonsils, nails, and teeth, the diagnosis of *chronic nasal catarrh* can be made.

Congenital Malformation.—While causes operating upon the fetus may be said to create the conditions which have just been recognized, it is also true that an entirely distinct class of pre-natal influences is effective in creating nasal catarrh. In a case of absolute atresia of both nasal chambers—with which condition was associated defective speech—the effect to the ear of the listener was almost identical with that produced in cases of cleft palate, notwithstanding the fact that the palatal and the pharyngeal mechanism were normal. In another case, that of a child three years of age, it was noticed that after an attack of scarlet fever the child could no longer breathe through the nose. The parents were inclined to attribute this condition to changes brought on in the nose by the attack of illness. Inasmuch, however, as the left side was absolutely occluded and the right side merely permitted a cotton-tipped probe to pass through into the pharynx; and in addition, the fact that the hard palate was narrowed and very high arched, while lachrymal obstruction and fistules existed on both sides, being more on the left, the conclusion was drawn that the condition was congenital, and was due to errors in the formation of the bones of the face. In this case

the angles of the mouth were excoriated, the cervical lymphatic glands were enlarged, and the existence of congenital syphilis was evident, although the teeth were not pegged nor the cornea hazy.

Effects of Local Injury.—The extent to which local injury influences the shape of the nasal chamber has a special bearing upon the subject of nasal catarrh in children. As a result of the frequent falls upon the face, it has been assumed that the deflection of the nasal septum, which is so common in the adult, may arise from this cause. While it is conceded that blows on the nose may deflect the septum, and thus induce obstruction and nasal distress, it is in the experience of the writer a rare occurrence. He has met with four cases only of such a condition, and in one of these a marked hereditary condition existed in other members of the family to nasal catarrh.

Prognosis.—The prognosis of simple cases of acute, and of subacute nasal catarrh is always favorable. The prognosis of the chronic cases should be guarded. Success depends to such an extent upon the recuperative power of the constitution of the patient, and to the character of the surroundings, that it is difficult to fix upon any one issue to all cases. It has already been seen that if neglected, the disease may be as noticeable in adult life as in childhood. Assuming the premises as to the nature of chronic nasal catarrh to be correct, it is evident that a cure cannot be expected until the development of the larger medullary cavities of the bones is completed. Under appropriate treatment the disease is so far kept under control that all suffering abates and disappears, at the same time that the general system remains in an unsatisfactory state. Of such cases, a reasonable hope may be held out that the disease will be entirely cured by the twenty-first year.

Treatment.—The details of the treatment may be embraced under the following heads:

(1) Removal of the obstruction of the discharges and the reduction in size of the swollen membranes.

(2) The applications of mercurial ointment to the vestibule.

(3) Straightening the nasal septum and overcoming atresia.

(4) The administration of general tonics, etc.

(1) The removal of the daily accumulation of the discharge in the nose and naso-pharynx is a matter of great moment. If the discharge is in the nose, it may be removed by dropping into the nose by a pipette (the head being thrown back) a few drops of a detergent lotion. In a short time

time the fluid is felt in the throat. It is very gratifying to notice the prompt relief which follows the judicious use of such remedies to the nasal mucous membrane, particularly, if the medicine be allowed to trickle in small quantities along the lower border of the inferior turbinated bone.

When a mucoid discharge collects in the naso-pharynx, it is best removed by the use of the pharyngeal syringe. The instrument used should be smaller than the one sold under this name. An instrument of convenient form can be improvised by attaching an Eustachian catheter to the nozzle of a No. 1 India rubber syringe, or to the smaller syringe used by dentists. The rule should be subject to no exception that the liquid is to be placed above the palate with the greatest care and gentleness, and a very small quantity, not over twenty to thirty drops of the liquid thrown in. After the instrument has been withdrawn, the head is bowed and the fluid is invited to flow through the nose and to trickle from the nostrils. A child who has had the instrument used with violence, will never consent to a second application. It must be remembered that the naso-pharynx in the child is very small, and becomes reduced to a mere chink when constricted, as at the time of the introduction of the nozzle of the syringe. The fluid thrown in cannot return into the oro-pharynx, but must flow forward. Should force be used by sending into the chamber a larger quantity of liquid than it can retain, and obstruction be present in the nasal chambers, the fluid will be exceedingly apt to pass up in the ears. Too much stress cannot be laid upon this source of danger, for, with the general disuse of that dangerous instrument, the nasal douche, in children, the impression is received that the pharyngeal syringe is a safe substitute. It is in the writer's judgment but little less dangerous than the douche, indeed, the source of the danger to the ears is precisely the same in the two instances. No doubt the physician can use the douche without danger, as he can the syringe, but if he habitually uses an instrument from which no aural complication can possibly arise, he is then, and then only, absolutely safe.

A few moments after the first application, or toward the close of the first sitting, the handkerchief having been used by the child, large quantities of mucus or muco-pus are removed, and the little patient is made relatively comfortable for a period extending from several hours to a day. Any detergent dissolved in tepid water suffices for the purpose of making these applications. No

specific action of drugs is to be anticipated. Weak solutions of carbolic acid and glycerine, namely about a drop of the acid to two drops of glycerine dissolved in an ounce of water, is as good as any. Boracic acid in almost any strength; common table salt; potassium chloride; are all in use with physicians, and are found efficient. It is not so much the remedy selected, but the manner of using it, that should receive attentive care. The use of astringents so universally mentioned, such as the preparations of tannin, of zinc, etc., can be, in the judgment of the writer, discarded. As for the preparations of iron, they are without exception mischievous.

(2) The condition of the floor of the nasal vestibule almost always demands attention. The use of mercurial ointments, such as are employed by oculists for blepharitis and granular lids, is followed by most encouraging results. The ointment of the red oxide of mercury, in the proportions of one grain of the salt to one drachm of cosmoline, is well borne. The ointment is best applied with a camel-hair brush to the interior of the nostril before retiring. An occasional application in the office to parts not accessible by an untrained hand is advantageous.

(3) The operations for misplaced nasal septum present no peculiar features in children, and the consideration of the procedures need not be undertaken here.

(4) In order to correct the discharge, which is apt to be of a simple character, it is necessary to care for the general health. The extent to which the tonsils should be reduced in size is to be determined by the degree in which they obstruct respiration. Should the premises given above respecting the etiology of the affection be accepted, it is evident that the tonsils need not, and indeed should not, be excised unless they are known to interfere with respiration, in which event they should be removed without hesitation.

BLOOD-LETTING IN THE OLD.

BY HIRAM CORSON, M. D.,
Of Conshohocken, Pa.

One who has read the paper which I wrote on the treatment of pneumonia by blood-letting, wishes to know whether bleeding would be admissible in these diseases in old people and in children.

I have observed, in talking with practitioners not wholly opposed to bleeding, indeed who occasionally use it, that they justify themselves in doing it, "because the patients were *strong, healthy, plethoric*

people." They based the propriety of the bleeding on the fact that these conditions existed, and not on the more important fact, that the loss of blood was essential to the speedy relief of the inflammation. My action in bleeding for the relief of inflammatory affections is based on the latter proposition without regard to age. In the present paper it is not necessary to speak of bleeding as a remedy in acute inflammation of important organs; *that* has been done sufficiently. Here I will give a few cases to show its value in other less striking, but more insidious and often not less fatal maladies, in persons of advanced age and children of only a few years. In doing this, I need not go back for cases which occurred long since, when bleeding was a popular remedy with physicians, and patients readily assented to being bled and cupped or leeches. These would not serve my purpose, for many of the opponents to the lancet admit that bleeding might have been very useful many years ago; but it is believed by them now that at some time since the advent of the cholera in 1832, and more especially since its reappearance in 1849, a great change has been effected, either in the nature of our diseases, or in the human system, or perhaps in both; they can't tell how it is, but they declare there is a change. Some are sure that the change is in the disease, others think it is in the system. They say: "The early settlers, who used to rise with the sun and labor all day, were strong and hardy, and could therefore bear depletion; but our people now have other habits, and are weak and nervous." It is not a little amusing to hear a man who has practiced only five or ten years talk about the conditions of disease and the human system as they presented themselves before he was born, as though he knew all about them, and yet refuse to listen to those who have lived and practiced through all the years in which these changes are supposed to have taken place. While I might report scores of cases of blood-letting in very aged people, bled with good effect many years ago, I shall for the reason already assigned pass them, and take those that have recently occurred, some even within a few weeks.

On the second day of the present June, 1881, I was called to see I. G—, aged sixty-nine years. He has been poorly for several days—indeed, for some weeks had not been able to do work in his garden—on account of giddiness and pains in all his limbs, which he thought was owing to constipation. I found him with a pulse of 76, entire loss of appetite, and inability to even sit up for more than a very short time. Cathartic pills and

aperients were given, and repeated so as to remove constipation, but in four days there was no relief. To use his expression, he "was sick all over the body as well as in the head." I bled him fourteen ounces. Next day found he had rested well, and his head was relieved. In two days, as I passed his house, I saw him sitting on the piazza, and he said he was quite relieved.

2. I was called to see Mrs. Cline on the 2d of May. She will be eighty-nine on December 20. She is a thin, spare woman, takes but little exercise—save a visit now and then to the neighbors, or to church, which is but a few hundred yards away. She said: "I have no peace with my head." Had a slight paralysis, she thinks, a few weeks ago. She had taken "physic" days before, but got no relief; had taken laudanum also, but was still suffering. I bled her only eight ounces, when the pulse which had been irregular became quite steady and regular, and I took no more. Two days after, I saw her, and she was quite free from pain or other suffering in the head. She is still free from pain, and moves about the house with considerable alacrity.

Three years ago a medical man of seventy-two years had been, for a few days, having an unpleasant feeling in his head. It was not a pain, but a dull, unpleasant sensation. Finally he arose one morning with an increase of the dullness and heaviness; and knowing how many persons during his long practice, had at that, and even earlier ages, dropped in a moment with palsy or apoplexy, after suffering from such feelings for a few days, many of them, as he believed, for lack of bleeding to relieve the oppressed brain, he concluded to be bled. Calling an assistant, he bled himself until he felt relieved, felt that the pressure on the brain was removed. The blood was set aside, and after awhile, feeling great relief, he was curious to know how much had been needed to give him so much comfort. On careful measurement there was found to be one quart—32 ounces. I saw him next day, and never did I see him in finer spirits, or in the enjoyment of greater apparent health.

3. A few years since I was called to a plethoric woman, over 56 years of age, who complained of "dullness and heaviness in my (her) head," not severe pain, but "a distressing feeling." She was sitting in the chair because she was easier than when lying in bed. I proposed bleeding. She had been greatly opposed to it for many years, was somewhat of a Thompsonian, and strongly wedded to No. 6, but she consented. I bled her

largely with some immediate relief. On my visit next day, she was found to be lively and well, and as a confession that she had not acted wisely in her long opposition to its use and her denunciation of it to others who might have been greatly benefited by it, she said: "I cannot tell any one how great was the relief obtained from the bleeding. I never could have believed it without this experience."

4. Mrs. N. J., a stout, fleshy woman in her seventieth year, sent for me June 14th, of the present year. For a week or more she has not felt well—has been languid, weary, and not quite right in the head. When awaking in the morning, or in the afternoon after a nap, she would feel so exceedingly weary and languid that she would not be able to rise, but after getting up she would stay up and go about the house directing affairs, yet all the time feeling exceedingly unwell. During the last three days another symptom has been present; when looking directly at an object, she would soon lose her sight; could not see it until she would turn her head and look at it sideways. This blindness has increased, so as to occur at short intervals, even when not looking specially at an object. Her face was not flushed, but had an expression of weariness; her pulse was strong, but only 70 per minute; the bowels were not costive—such was her condition. Was there danger in it? Yes, infinite danger—thousands had passed suddenly from that condition to unconsciousness and death. What should have been done to avert such an ending? Aconite and veratria were not called for by the condition of the pulse—quinine, or chloral, or bromide potassium, says some one—would have been the proper measure. I had used them in other cases not very unlike this one, but never with prompt and satisfactory results; so, instead of using them, bled her twenty ounces, while she was sitting up, and with some relief, diminishing slightly the strength of the pulse, and producing a lighter feeling in the head. It was then evening, and she retired for the night. The next day she was entirely free from any affection of the head, and the languid, weary feeling had passed away. From that time she was well.

(To be continued.)

ON PUERPERAL ECLAMPSIA.

BY D. MONROE, M. D.,

Of Cameron, Texas.

The pathology of puerperal eclampsia continues so mystified by the confusion of conflicting theories advocated and advanced by the learned ob-

servers, from the days of Hippocrates to the present time, that the student is more confounded than the builders at the tower of Babel.

Each pathologist advocates his line of treatment to conform to his own brilliant theory; hence such chaos as regards treatment.

After considering the mechanical, albuminous, uræmic, and anæmic theories, the latter a very anæmic one indeed, we come to the more plausible theory of Marshall Hall, the reflex motor action of the nervous system.

When the spinal marrow, the central organ of this system, has been acted on by an excited condition of an important class of its incident nerves, and this impression transmitted through the spinal centre, as an excito-motor centre, thence by reflex action over the whole muscular system, giving rise to a convulsion, whether such focus of irritation be hardened wax in the ear, carious tooth, undigested food in the alimentary canal, ascaris in the rectum, or a fetus in utero.

This morbid irritability of the womb, either from hyperæmia or anæmia, kept up by the presence of the fetus producing distension and tension of those irritated sentient nerves, causing this excito-motor radiation, known as puerperal eclampsia.

Accepting this as the true version of the cause of puerperal convulsions, the therapeutic remedies to be of use readily suggest themselves.

The first indication in the treatment is to guard the brain from undue blood pressure; the second, to prevent a recurrence; while the third is to remove the cause.

The subcutaneous injection of veratrum viride, or aconite, would fulfil the first indication; while chloroform and chloral hydrate meet the second by depleting the brain and its sedative powers over the nerve-centres, aided by the subcutaneous injection of *f. ex. gelsemium*, the therapeutic property of which is to abolish reflex power, by its direct action on the spinal cord, and through the same channel diminish the voluntary power. Hence we have in *gelsemium* a remedy which fulfils the indications exactly, accepting the theory of Marshall Hall. And we hold that no puerperal woman can have a convulsion when thoroughly under the influence of this remedy.

Calabar bean paralyzes the spinal cord, much in the same way as *gelsemium*; why not try it, as the calabar bean will control strychnine convulsions.

To comply with the third indication, we must

get rid of the focus of irritation—the fetus—as soon as practicable. Dilate with Barnes' dilator, if need be; and then deliver with forceps.

Case 1. Was called to see Mrs. —, æt. 18, primipara; found midwife in attendance, and was informed that Mrs. — was having "strange spells," and had been having them for several hours. Made an examination, and found vertex presenting and in inferior strait. Was told by the midwife that things had been in statu quo for seven hours.

In a few minutes, I fully realized what those "strange spells" were; that they were in reality that alarming foe, puerperal convulsions.

I immediately began the administration of chloroform, and sent after Dr. —, with orders to bring his obstetrical bag.

As soon as the convulsion ceased, I administered, hypodermically, *f. ex. gelsemium*, gtt. xij., and *veratrum viride*, gtt. iv. The pains being feeble, short, and inefficient, the os dilated and no contra-indication, as soon as she could swallow, I gave per orem liq. ergotæ purificatus, gtt. xxx.

In less than an hour, and before aid and instruments arrived, she was delivered of a large still-born child, without a repetition of the convulsions, and no hemorrhage.

The placenta being retained by an hour-glass contraction of the womb, we administered chloroform and removed it with the hand.

The child had convulsions, due to pressure of the cranial bones on the cerebrum, owing to ill-shape from pressure, for twelve hours after birth, whenever the chloral hydrate and bromide mixture was delayed too long.

Case 2. Called in consultation with Dr. — to see Mrs. —, æt. 34, in her fourth confinement. Was informed she had had already four convulsions; and was then in a semi-comatose condition. She had been bled freely from both arms, and had taken morphine sul., gr. ss., with hyd. chl. mit., grs. xx per orem.

We immediately gave *f. ex. belladonnæ*, gtt. iij., hypodermically.

In two hours was seized with the fifth convulsion, a very severe one indeed. Then we gave, hypodermically, *f. ex. gelsemium*, gtt. x. And in less than five hours she had her sixth and last convulsion, when we gave, hypodermically, *f. ex. gelsemium*, gtt. xij., and repeated the same dose in three hours. Again in four hours we gave, hypodermically, gtt. xv.

In five hours from this time she was delivered of a fine child, almost without a pain and no hemorrhage. Both mother and child did well.

DESTRUCTION OF SMALL ENCYSTED TUMORS BY CAUTERIZING THEIR WALLS.

BY LEVI W. HALSEY, M. D.,

Of Bridge Hampton, N. Y.

On June 16, 1883, Miss B., a German girl about twenty-five years of age, came to my office to consult me in regard to a bunch situated upon the back of the right forearm, immediately above the wrist joint. The tumor was as large as a hen's egg, soft to the touch, and slightly movable beneath the integument in all directions. By pinching the skin directly over it, I found it was free to move, thus showing that if closely connected at all it must be around and below the growth. It occasioned little pain except when the arm was actively employed; but the patient, being a hard-working domestic, suffered somewhat, and consequently sought to have it removed.

Mention of enucleation only alarmed her, and she positively refused to submit to an operation, desiring that I should give an ointment or application of some description, in any of which she professed great faith. I suggested the advantage of a more rapid extirpation, though without avail; so a prescription of iodoform and vaseline was given, to be applied twice a day.

After a week, as I had confidently anticipated, she returned, bringing with her a friend, and asked to have the tumor removed at once with the knife. Some influence had led to a change of mind, possibly the disgusting odor of the prescription recommended had its effect.

Thinking the mass could be easily enucleated, an idea which the examination fully warranted, and the patient seeming to have sufficient courage, I proceeded to operate without an assistant, as no anæsthetic was to be used, she preferring to do without one.

As is usual in removing small encysted tumors, a long incision was made through the integument, exposing the upper portion of the sac. I then endeavored to turn out the whole growth by passing the handle of the scalpel around it: these attempts were futile, as were all efforts to cut it out; for the sac walls were so firmly adherent to the adjacent tissue that they could not be separated unless the whole was removed in a lump. The latter alternative I did not care to adopt, as it appeared now to be more deeply seated than was at first suspected. Just at this juncture my patient was taken sick at the stomach, and then fainted. I hastily directed the young lady's friend to lower her head and dash water over her face and temples, and at the same time to hold a bottle of aqua ammonia at the nose. I then divided the

sac through its whole extent, and evacuated its contents—a thick, viscid, glue-like substance. It was thoroughly cauterized with the first thing I could select from my case, a strong solution of the chloride of zinc. The edges of the wound were carefully adapted, and retained in position by two sutures and adhesive plaster. Iodoform dressing was used to secure antiseptis. The arm was placed in a sling, and the patient ordered to refrain from work. Through the whole course of the incision healing was by first intention, except the lower portion, which was intentionally left open, that all pus and any unhealthy secretions might be discharged.

Suppuration was not profuse at any time, yet sufficiently so to effectually destroy the sac. The young lady experienced no inconvenience from the operation, save for the time the arm was carried in a sling. No change was made in the dressing, the first preparation being continued until granulation was complete and the whole wound closed. Free use of the arm was allowed after two weeks, without any bad effects resulting therefrom.

Now, after seven months, only a fine red line, marking the cicatrix can be seen where before was situated the unsightly bunch.

The success of the procedure was such that I should operate in like manner in all cases where the sac is found to be closely connected with the surrounding parts.

Destruction of small tumors by cauterization and consequent suppuration is not a new, but, in fact, an old way of proceeding; yet it is far preferable to the cutting and tearing so often witnessed in the attempt to extirpate small growths which are not readily enucleated.

Turn out the whole mass if it can be easily done; otherwise irritate the walls after its contents have escaped, and they will destroy themselves.

FATAL CEREBRAL EMBOLISM.

BY GEO. H. GOODE, M. D.,

Resident Physician Western Pennsylvania Hospital,
Pittsburgh, Pa.

J. G., æt. 27 years, was admitted to the Western Pennsylvania Hospital July 30, 1883. At the time of his admission, he was suffering with a stricture of the urethra. He had been under the care of Drs. Daly and Kersey for some time before his admission to the hospital, and the previous history of the man's case, as obtained from them, was simply as follows: Nine years ago he con-

tracted a gonorrhoea, at which time the urethra became strictured. Several times subsequently he had suffered with epididymitis. When Drs. Daly and Kersey saw the patient he was suffering with retention of urine, and an attempt was made to pass a filiform bougie into the bladder, and with success, but it was not possible to pass the tunneled sound. Drastic purgatives were administered, and at a subsequent attempt made on the following day, the physicians were able to pass several filiforms. The patient was then advised to go to the hospital.

Dr. Jas. McCann saw him, and was able to pass a No. 5 steel sound into the bladder. The stricture was dilated still further, by the use of sounds of larger size, which were passed with some little difficulty. After the use of the instruments, the patient had a chill, followed by elevation of temperature, indicating the occurrence of urethral fever, which entirely subsided by the next day.

On the following day (August 3) he complained of pains in his shoulder and elbow-joints, and said that he had had rheumatism several years ago. His heart was examined, and a distinct mitral regurgitant murmur was elicited. Salicylate of soda was administered in fifteen-grain doses every four hours. In the evening he expressed himself as feeling very well, and conversed very freely with a party of friends who had called to see him.

Early the next morning (August 4), the nurse called the resident and told him that the patient was snoring very loud, and could not be aroused. When seen by the resident, violent efforts were made, which proved of no avail in bringing out any signs of consciousness. He was breathing stertorously; at first there was nothing very marked in the appearance of his pupils, but later the left pupil became much more dilated than the right; the right side was paralyzed. The diagnosis made from these symptoms, in connection with the mitral murmur, was cerebral embolism. The patient continued steadily to grow worse, and died about five o'clock of the same day. On post-mortem examination an immense clot, which filled a greater part of the left cerebral hemisphere and breaking into the right, was found, thus proving the correctness of the diagnosis. The heart was examined, and upon the mitral valve vegetations were found. The kidneys and spleen were also unhealthy.

—Codeine phosphate has been prepared by Merck, at the suggestion of Prof. Hegar. It is soluble in four parts of water, and is suited for hypodermic injection.

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL.

BY CHARLES K. MILLS, M. D.,

Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic; Neurologist to the Hospital.

Reported by WILLIAM H. MORRISON, M. D.

(Continued from page 233.)

Organic Hemianæsthesia; Methods of Studying Sensory Disturbance; Differential Diagnosis of Organic from Hysterical Hemianæsthesia.

You should next study the electro-sensibility. In doing this a rapidly-interrupted faradic current should be used. With this, two things may be determined: (1) The muscular sensibility, by the use of moist sponges applied with pressure; and (2) The cutaneous sensibility, by the use of metal discs or a wire brush. In this patient the use of a powerful current, although it causes a response in the muscles of the left side, is not felt.

This case is one which deserves in every way the designation of organic hemianæsthesia. When a case of complete hemianæsthesia, with or without paralysis, presents itself, the first important matter is to decide whether it is a hysterical affection, which can be cured, or a condition, the result of an organic lesion, which is beyond the possibility of cure. Let me give you a few points in the differential diagnosis. I shall first indicate the points of apparent identity. A hysterical patient may have just as complete hemianæsthesia as this patient presents. I have seen such cases in which a thousand needles could have been thrust into the flesh without producing any complaint. In hysterical cases, motor paralysis and contracture may also be present. The anæsthetic condition, moreover, may have continued for years, as it has in this woman. Other points of apparent identity might perhaps be mentioned.

In the differentiating of hysterical and organic hemianæsthesia, the history is important. The precedent history of these two affections is different. In the one you have a history of the hysterical diathesis; in the other, not. In the organic case, you have an apoplectic attack of a peculiar kind. The patient suddenly loses consciousness, and the temperature and pulse variations are peculiar. These are associated with special respiratory phenomena, perhaps with the Cheyne-Stokes breathing. The patient remains in a condition of absolute unconsciousness to all methods of investigation for a greater or less time, not simply in hysterical coma. Hysterical hemianæsthesia does not come on in this way. The patient may have hysterical spasm or coma, and remain in a condition of apparent or partial unconsciousness, but she will not have the peculiar phenomena of pulse, respiration, and temperature, which attend the apoplectic attack, and which were present in this case.

In hysterical hemianæsthesia, ovarian hyperæsthesia and hystero-epileptic seizures have usually been present; and you may have also ischuria and other well-known hysterical symptoms, none of which have been present in this case.

The anæsthesia in hysterical cases is most commonly on the left side of the body, but so it happens to be located in this case, so that this point is only one of slight value.

The paralysis and contractures, if present, as in this case, are apt to be accompanied in organic cases, after time has elapsed, by marked nutritive changes, by wasting of muscle, and even of skin and bone. This is not the case in hysteria.

Some of the older observers, as Briquet, who is quoted and criticised by Charcot, believed that hemianæsthesia from encephalic lesions differed from hysterical hemianæsthesia by the fact that, in the former case, the skin of the face did not participate in the insensibility, or that, when it existed, it never occupied the same side as the insensibility of the limbs.

Many recently reported cases have disproved the accuracy of this supposed diagnostic mark.

In his lectures, delivered nearly ten years ago, Charcot observed that up to that period anæsthesia of general sensibility alone appears to have been observed as consecutive on an alteration of the cerebral hemispheres, so that obnubilation of the special senses would remain as a distinctive characteristic of hysterical hemianæsthesia. He, however, expected that cases of cerebral organic origin would be reported, of complete hemianæsthesia, with derangements of the special senses, such as is presented in hysteria. His anticipations have been fulfilled. A number of such cases are now recorded. The present case is one in which the special senses are partially involved.

After the patient comes out of the attack, certain trophic changes occur in the apoplectic form, which do not appear in the hysterical variety. These are the acute bed-sores, and have been present in this case. The subsequent history of these two conditions is different. The hysterical patient will often recover and relapse, or, under proper treatment, may recover entirely; while all the treatment that can be given to a case of organic hemianæsthesia will produce no decided improvement, for there is a lesion in the brain which will remain forever.

We can say with some positiveness where the lesion is located in a case of this kind. It has, I think, been demonstrated that a certain region of the brain is concerned with sensation, or, at least, with sensory perception. Speaking generally, this, according to Fenier, is the parieto-temporal region. According to the same authority, the hippocampal convolution is especially connected with tactile sensibility. The optic thalamus is also in some way connected with sensation, and Lays goes so far as to contend that in this body are special centres for different forms of sensation. Unquestionably certain of the white fibres of the brain convey sensory impressions. This has been abundantly proved by autopsies and experiments. Section or destruction by disease of the upper posterior part of the internal capsule is followed by hemianæsthesia of the opposite side of the body.

This woman has had a clot or other lesion, which has destroyed the upper and posterior part of the internal capsule, and involving also the adjoining part of the lenticular body, the latter accounting for the motor paralysis. Another cerebral lesion which could cause these symptoms,

would be a diffuse lesion involving the sensory centres of the cortex. If it were a lesion of these centres, you would not be likely to have such complete anæsthesia of other regions as in this woman. As a matter of fact, for vascular reasons, the lesion is more apt to occur in the region previously mentioned.

Lesions of the optic thalamus also cause hemianæsthesia of the opposite side of the body; but whether by pressure on the internal capsule, or by direct effect, has not yet been satisfactorily determined.

In confirmation of the pathological diagnosis just made, I will read to you the condensed account of a case which is in almost every respect, except that the right side and not the left was affected, a counterpart of the one now before us. The symptoms presented are very carefully described, and the results of a post-mortem examination are given. The paper containing this excellent report is by F. Müller (*Berl. Klin. Wochenschr.*, 1878, No. 20, quoted in *Brain*, April 1878.)

The patient was a man, aged 61, suffering from chronic alcoholism and aortic insufficiency. About seven weeks before admission into hospital, he complained of headache, constantly increasing in severity, and of feelings of numbness, tingling, and creeping in his right arm. In a few days these symptoms were succeeded by an apoplectic seizure, with right hemiplegia and loss of speech. Speech was regained in eight days, and in fourteen days the patient was so far recovered that he could leave his room and attend to his business; he only felt a weakness in the hand and foot of the right side. He was admitted into the hospital, complaining of headache and cough. An examination of the nervous system revealed slight right hemiparesis; the movements on this side were somewhat weak, but were regular and well co-ordinated; on walking with the eyes closed, there was no evidence of ataxia. There was complete right hemianæsthesia. The patient was not aware of the loss of sensation, and was quite surprised at experiencing no pain on being pricked with a pin. The hemianæsthesia was slightly limited by the median line. The bones had lost their sensibility. Pressure over the liver was slightly felt. Tickling and pinching of the upper and lower extremities were followed by reflex movements; tickling of the right external auditory meatus was without effect. The conjunctiva and cornea, and the mucous membranes of the cheek, tongue, soft palate, uvula, nostril, glans penis and arms, were quite anæsthetic. There was a total loss of the muscular sense on the right side. Patient could not distinguish between objects of different weight; he was ignorant of the position of his limbs at any movement; and if told to move a limb, the movement being forcibly prevented, he would make an effort for a time and then cease, thinking the movement had been accomplished. The sense of temperature was lost on the right side. There was almost complete amblyopia of the right eye; the ophthalmoscope revealed nothing in the fundus which would account for this. The left eye was quite normal, and showed no trace of hemiopia. Hearing was so far affected on the right side that the ticking of a watch was only heard when the watch was in contact with the

ear; on the left side it was heard with the watch at a distance of 50 cm. Smell was completely lost on the right side, and taste was greatly impaired over the whole right half of tongue. The organs of sense on the left side were quite normal. Examination with the Faradic current showed complete loss of electro-cutaneous and electro-muscular sensibility; the minimal strength of current requisite to produce contraction was the same on both sides. The opening and closing shocks of a Stöhrer's continuous current battery of 30 cells, caused very powerful contractions, but no pain. On applying the negative pole to the upper eyelid (the lids being closed), and the positive pole to the cervical vertebra, the optical appearances known as Purkinje's figures were produced on opening and closing the current—in the right eye with six cells, Stöhrer, in the left eye with as few as two cells. On stimulating the right border of the tongue, there were muscular contractions, but no metallic taste. The patient died three weeks after admission of infarction of the right lung. On post mortem examination, a very sharply circumscribed focus of softening of the size of a pea, was found involving the apex of the third division (posterior point of external segment) of the lenticular nucleus and the adjacent white matter. Very careful examination failed to discover any other lesion. In discussing the case, the author quotes Pierret's statement that the hinder part of the internal capsule, or the adjoining part of the corona radiata, was found affected in thirteen out of fifteen cases of hemi-anæsthesia in which an autopsy had been made.

Returning to our patient, let me say in conclusion, that a number of experiments with metal plates, applied to the hemi-anæsthetic side, were made on this patient several years since, of which the following is an account. They are interesting, as showing how closely organic hemi-anæsthesia, even in this respect, resembles the hysterical affection:

On November 13, 1879, at 3.25 p. m., a copper plate was placed on the anterior surface of the forearm, immediately above the wrist. Half an hour later she complained of tingling and burning pain all over the forearm. The pain radiated along the ulnar side of the arm from the elbow to the wrist, and also around the edges of the plate. At 7 p. m. the plate was removed.

November 14, a zinc plate was, at 10.05 p. m., put on the arm just above the position previously occupied by the copper plate. About 4 p. m., she complained of burning pain over the arm from the shoulder to the hand. On the forearm the pain was described as being situated over the ulnar nerve, and also was felt beneath the plate, but not more distinctly than in other situations. The plate was removed at 7 p. m.

November 15, at 9.30 a. m., copper, zinc, and iron plates were applied. The iron plate was applied to the wrist, the copper plate to the middle of the forearm, and the zinc plate above the elbow. At 3.15 p. m. they were removed. She then complained of pricking sensations over the forearm on the ulnar side, and more especially beneath the copper plate. At 3.20 p. m. a copper plate was placed above the elbow, and an iron plate above the wrist. In half an hour she complained of burning pain in the middle of forearm, above the iron plate.

November 16, at 9 a. m., the plates were reversed, the copper plate being applied above the wrist, and the iron plate above the elbow. At 9 p. m. they were removed. At this time she complained of burning and throbbing pain over the whole arm, and the neck and shoulders, without reference to the plates, the pain coming on four hours after their application.

November 17, at 10 a. m., a copper plate was applied to the arm, and a zinc plate above the wrist. This was followed by pricking sensations from the elbow to the wrist, and burning pain to the neck.

November 18, at 10 a. m., iron and zinc plates were applied, the iron above the wrist, and the zinc above the elbow. They were removed at 7 p. m. She complained of burning pain over the arm below the elbow, and also of a sensation as though warm water were falling on the hand.

It will be observed that no transfer phenomena—no transfer of sensation or of loss of sensation—were at any time noted, an effect which is often produced in hysterical cases.

BELLEVUE HOSPITAL, JANUARY 5, 1884.

Reported for the MED. AND SURG. REPORTER by J. H. WOODWARD, M. D.

The cases incorporated in this report were treated under the supervision of Dr. Chas. McBurney, in this hospital. Their histories are offered for publication, because they form a series of consecutive cases, treated in the same general way, and with the same general result.

Case 1. Gun-shot Wound of the Thigh.

Robt. DeW—, æt. 26, was admitted to ward 10, November 29, 1883. A short time before his admission he had received a bullet wound in his left thigh. The wound of entrance was about three inches vertically below the anterior superior spinous process of the left ilium. No wound of exit was to be found. About four inches below the tuberosity of the left ischium, on the inner surface of the thigh, there was a large swelling, which had formed suddenly after the shooting. Both tibial arteries were pulsating. Patient was not heavily shocked, and he had not lost very much blood.

The house surgeon made an incision on the inner surface of the thigh, extending into the tumor already mentioned. Through this wound a 38-calibre bullet was extracted. A considerable quantity of clotted blood flowed from the thigh; but the thigh still remained enlarged in this region. An attempt was made at this time to pass a uterine probe through the bullet wound from the wound of exit to that of entrance. The probe deviated from the track of the ball, and its point was detected beneath the integument, one inch below the anterior superior spinous process of the ilium. It was exposed by an incision. A long piece of fenestrated rubber tubing was fastened to the point of the probe, and drawn through the thigh and secured in that position by a safety-pin at each end. A large tube was inserted into the region occupied by the extravasated blood, and another into the wound of entrance. Safety-pins were passed through these tubes to hold them.

They were then flushed with solution of corrosive sublimate in water, strength 1-2000. The wounds were dressed with iodoform, carbolized gauze wet in 1-40 carbolic solution in water, and borated cotton. The dressing was large and thick.

Full antiseptic precautions were taken during all these manipulations and at the subsequent dressings of the case. The thigh was washed carefully with 1-40 carbolic solution before anything was done to the wound. After having disinfected the part in this manner, it was irrigated with the solution of corrosive sublimate in water, gr. iv. to vj. This irrigation was nearly constant from the time it was begun until iodoform had been sprinkled upon the wounds. The hands, instruments, and sponges were rendered aseptic by carbolic acid, and the drainage-tubing had been immersed for weeks in a five per cent. solution of carbolic acid.

Nov. 30. Highest temperature since the shooting, $99\frac{3}{4}^{\circ}$. The discharge of bloody serum had penetrated the dressing, and a fresh one was applied. Ordered quinine gr. ij., and liq. morphine U. S. $\frac{3}{4}$ ij. t. i. d.

Dec. 3. Highest temperature since the last note, 100° . Re-dressed the case again to-day because the discharge had appeared again. No pus in the dressing. Washed out the tubes with bichloride solution. A similar dressing to that first applied was placed upon the wound. Two hours later, while the patient was straining at stool, a pretty severe venous hemorrhage came from the wound. Examined the wound at once, and found that the hemorrhage had ceased. The thigh was still considerably swollen, and presented a few traces of ecchymosis. Re-dressed as before. A second attack of hemorrhage occurred about an hour later, due to the same cause. The wound was examined immediately; the hemorrhage had ceased. Re-dressed as before. Stopped the morphine.

Dec. 5. Re-dressed the case in order to remove the drainage-tubes. Found the discharge small in amount and not purulent. Forced the bichloride solution through the thigh. Same antiseptic dressing as before. Highest temperature yet recorded in the case, $100\frac{1}{4}^{\circ}$. Average temperature, $99\frac{1}{4}^{\circ}$. Ordered lead and opium pills to constipate his bowels.

Dec. 10. Temperature range since the last note has been below 100° , excepting two rises to 100° on December 6. Patient vomited this morning, and again venous hemorrhage occurred from the thigh. Re-dressed the case as before, and found that the hemorrhage had ceased. Thigh is considerably larger than it should be, owing, no doubt, to the presence of extravasated blood. A rubber bandage was passed over the antiseptic dressing to make moderate compression of the wound. Stopped the lead and opium pill. Ordered calomel, gr. x.

Dec. 11. Bowels moved this morning. No recurrence of hemorrhage.

Dec. 13. Redressed as before. A small quantity of pus discharged from the wound on the inner side of thigh. Inserted a short rubber drain into this region. Thigh still swollen, but not tender; spots of ecchymosis over the swollen portion.

Dec. 14. Removed the rubber bandage. Ordered ferri et strychnie citratis, gr. v., t. i. d.

Dec. 17. Redressed as before, and removed the

tube. The discharge was trifling in amount, but purulent.

Dec. 21. Redressed. No pus in the discharge.

Dec. 28. Redressed. The wound has healed, and there remained only three small superficial ulcers. There is still a hard tumor on the inner side of the thigh. The temperature range since the 10th inst. has been below 100° .

Jan. 1. Allowed the patient to sit up in a chair.

On the 5th, he was allowed to walk about the ward at will.

Jan. 10. He was discharged, the wound perfectly healed; the tumor had disappeared, and the patient was as well as ever.

The hemorrhages were severe enough to warrant the supposition that the profunda vein had been cut by the bullet, and considerable anxiety was felt lest the patient should become sanguinated by repeated hemorrhage. A reasonable fear was entertained that the blood extravasated into the deep tissues of the thigh might form the focus of an abscess. Had the wound been treated with less thorough antiseptic precautions, there can be little doubt that abscess and prolonged suppuration of the track of the ball would have occurred.

It is proper to state here that it is not the custom in the service of Dr. McBurney to pass a drainage tube through the gun-shot wound before suppuration has occurred throughout it. In this case the drainage tube did not follow the course of the bullet, but opened up the planes of muscles at other points. By this, damage was done to the tissues of the part; but in spite of both injuries—that due to the bullet and that due to the drainage tube—the patient recovered, and he recovered without the production of more than $\frac{3}{4}$ ss. of pus in his wound.

(To be Continued.)

MEDICAL SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Report of the Committee on Meteorology and Epidemics for the Years 1881 and 1882.

BY JOSEPH G. RICHARDSON, M. D.,

Professor of Hygiene in the University of Pennsylvania, and Member of the Philadelphia Board of Health.

[Read December 5, 1883.]

Meteorological observations for the year 1881 show that the winter months, as exhibited more in detail by the accompanying tables, were decidedly colder than the average, January being 5.7° below the mean for the past twenty-four years. The early part of spring was rather dry, but in June abundant rains occurred, and the average temperature was below the usual standard, although the entire summer average exceeded that of 1879 or 1880. The temperature of November was 4.5° above the mean, and but little ice or snow appeared during the following month. The most elevated temperature was observed on the 7th of September, when the thermometer rose to a height of $101\frac{1}{2}^{\circ}$. The lowest temperature was noted in February, when the thermometer fell to 1° ; the entire range for the year being

100.5°. The mean relative humidity was 70.3, and the total annual rainfall unusually scanty, only amounting to 30.21 inches.

The death-roll for 1881 comprised 19,515, or 22.48 per 1,000, being an increase over the previous year of 1804. Small-pox was by far the most prevalent among the epidemic disorders, causing death to 1,336 persons. Cholera infantum proved fatal to 902, scarlatina to 486, and diphtheria to 457 individuals. Typhoid fever was much more prevalent than in any twelvemonth since the Centennial year, and caused 645 deaths, 450 of these being among adults, and 195 children.

The early part of the year 1882 showed a rather low average temperature, the coldest weather in the two years now under consideration occurring in January, when the thermometer marked on one occasion half a degree below zero. The summer months were rather below the mean temperature for that season, and the maximum attained at the U. S. Signal Office exceeded 90° on two days in June, and six days in July only. The rainy season set in early, six inches of rain falling in August, whilst in September the precipitation reached the extraordinary amount of 12.09 inches. The total annual rainfall was 45.58 inches, being more than one-half greater than that of 1881. Rain or snow fell on 118 days during the year.

The mean temperature during the year was 54.6°, with a range of 94.3°, extending from a minimum of 0.5° below zero in January to a maximum of 94° in June.

The total mortality for 1882 was 20,059, or 22.62 per 1,000, being an increase over the previous year of 544. Smallpox, although much diminished in frequency, continued to rage with alarming severity, proving fatal to 314 persons. Diphtheria was the gravest epidemic disorder, causing 933 deaths, whilst the epidemic spread of scarlatina was so far diminished that only 310 individuals fell victims to that disease. Cholera infantum levied almost its usual tribute upon the rising generation, cutting short 871 lives.

A gratifying feature in the mortality reports of 1882 is the increase by nearly 12 per cent. of the number of people dying from old age, which proved fatal to 824 individuals; of these, 14 were recorded as being between one hundred and one hundred and ten, and one as being over a hundred and ten years old.

Although diphtheria has of late become increasingly and alarmingly prevalent in Philadelphia, our most serious epidemic disease during the past two years has been smallpox; and the obstinate continuance of this loathsome malady among us, as well as its gradual recrudescence from time to time, seems to call for renewed, and if possible improved measures towards its suppression.

The following suggestions having for their basis that principle of justice which prohibits men from even carelessly and unthinkingly injuring their neighbors, are submitted as a preliminary step to the establishment of some more efficacious plan of action for preventing the spread of epidemics.

Our efforts in this direction can perhaps be aided by diligently teaching our patients, when opportunity serves, the doctrine of disease-germs as held by most progressive physicians at the

present day. Indeed, the diffusion of popular knowledge upon this subject is, I consider, of immense importance from a sanitary, and especially from an epidemiological point of view, because as soon as the public is convinced that small-pox, diphtheria, typhoid fever, etc., are alone propagated by tangible and microscopically-visible germs or seeds, which are carried from the sick to the well, isolation and disinfection will be regarded not merely as hitherto in the light of wise precautions, but as imperative duties for every conscientious and law-abiding citizen.

The knowledge we now possess of the germ theory of disease, lends a new and stronger emphasis to the eloquent statement of Prof. Aiken in regard to the original spread and terrible fatality of small-pox in America from a single negro sailor, landed on the Mexican coast. "No common conditions of human life," he remarks, "gave rise to such phenomena as these. Propagation from the actual poison of a pre-existing case was the one necessary and all-sufficient cause for these endemic outbreaks of small-pox, and their epidemic prevalence. The precise mode in which the contagious diseases with their specific poisons first came into existence is beyond our ken—hidden from us as yet by a thick veil, and remaining an inscrutable, or at least so far an unpenetrated mystery. But everything tends to show that once created they all propagate only in one way—namely, by continuous succession."

An occasional failure to account for certain so-called idiopathic cases of contagious diseases, is only what we have in the nature of things to expect, and forms no evidence against the truth of this assertion of Dr. Aiken. For whilst we cannot always trace the obscure route by which germs of contagious maladies reach the healthy from the sick, most medical men in active practice are doubtless able to recall circumstances which go far towards explaining the mystery of their conveyance. Thus, for example, about twelve years ago there presented himself to me in the Out-patient Department of the Pennsylvania Hospital—a man covered with discrete small-pox pustules, who had been sitting muffled up and undetected, for more than an hour, in the waiting-room with twenty or thirty other patients, all unconscious of their danger of infection. In the epidemic of 1871-2 one of my patients whose nephew, a country lad here on a visit, was attacked with small-pox, dressed him up as a girl so that she could shroud him in a thick veil, and in spite of my remonstrances, took him by more or less crowded street-car, ferry-boat, and railroad train, to his home in New Jersey, of course at the risk of numerous lives. Again, during the same epidemic I attended two cases of variola in the family of a ready-made clothing dealer, whose coats and vests were probably all infected with the poison of small-pox, and went out of his shop on the backs of hundreds of customers, who were thereby subjected to the deadly peril of contracting that terrible disorder, without the slightest warning of their danger.

Admitting, then, that in some such modes as these the germs of every American case of contagious disease, occurring in the past two centuries at least, have emanated from some previous case, it is obvious that in a majority of instances,

a knowledge of the chance for such conveyance of the poison, in time to prevent it, was possessed by the patient and his friends or nurses only. Hence in striving to obstruct the progress of an epidemic, our efforts will be most apt to win success, if we can devise some means powerful enough to control the ignorance and carelessness of each patient, and those of his immediate attendants, from the earliest possible moment of the attack.

Such a check against the negligent as well as the wilful dissemination of disease germs, may I believe be found in some modification of the admirable proposition of Dr. Albert L. Gihon, Medical Director U. S. N., before the American Public Health Association, in 1881, and I therefore earnestly recommend it to fellow members of the College, for their individual consideration, perhaps at some future time for their official sanction and support.

Dr. Gihon, as Chairman of the Committee on the Prevention of Venereal Disease, presented a unanimous report, which contained the following section of a proposed act: "Be it enacted that any person within the limits of this State who shall knowingly communicate, or be instrumental in communicating, by any direct or indirect means, a contagious disease, such as smallpox, or scarlet fever, or venereal disease, shall be deemed guilty of a misdemeanor, and shall be subject, upon conviction in any of the Circuit Courts of the counties of this State, or in the criminal Court of the city of to a punishment of six months' imprisonment in the of"

Now, whilst I firmly believe in the strict justice and propriety of such a law as Dr. Gihon suggests, I fear that to urge it in its entirety at the present time in Philadelphia, would be making the grave mistake of trying to go too far beyond the present status of public opinion, and that even an attempt to punish the conveyance of the milder contagious diseases would not be sufficiently sustained by popular sentiment in our community.

But the horror of small-pox, which is often intense among populations in proportion to the density of their ignorance, would, it seems to me, so far aid physicians, and especially those of us who are members of the Board of Health, in an obviously judicious effort to obstruct the tide of its epidemic prevalence, that we might succeed in having passed and executed some law such as we have urged before our local legislators for two years, imposing a fine or imprisonment for the negligent or wilful transmission of that one disease, which would cause much greater care against the spreading of variola, to be exercised by those suffering from small-pox, or having charge of cases of that malady.

Our British cousins are far in advance of us in this respect, as is shown by the following extract from the *Sanitary Record*:

"At Athenry Petty Sessions (in Ireland), a shopkeeper in that town named Dillon was fined £3 and costs, with the alternative of two months' imprisonment at hard labor, for having, to the danger of the public health, appeared in public at Galway, while in the convalescent stage of small-pox."

What parent among us would not far rather a desperate highwayman should steal his watch,

than that a small-pox patient in the condition of this Galway scoundrel should simply brush against his unvaccinated child; and yet for the one crime the villain might be punished with years of imprisonment, whilst for the other, as the laws now stand here, no penalty whatever could be inflicted.

It perhaps would not frequently be necessary to institute legal proceedings against violators of a new law enacted to remedy this gross injustice, because, as a rule, the mere fact that a person might be compelled to suffer in person or estate, for injuring a fellow-citizen by infecting him with small-pox, would operate as a powerful check upon negligence, and could hardly fail to prove beneficial to us all.

As to the justice of punishing such instances of careless or wilful injury to life and health, it may be urged that murder by poison is just as much punishable by death, as is that by shot or steel, and that no valid distinction can be drawn between the moral guilt of one who kills his neighbor by giving him arsenic, and that of another who, under similar circumstances, causes the death of a fellow-being by giving him the germs (or poison, whatever it may be) of small-pox. If either crime is committed intentionally it ought to be adjudged a murder; and if done knowingly though without malice, or even ignorantly and carelessly, the homicide is still, it seems to me, deserving of punishment.

A man who empties his revolver into a crowd of people, would be held answerable before our courts for the lives of any who might be killed by his shots; and why should a person who emptied out from his lungs breath loaded with the germs of small-pox into the same crowd, be judged guiltless of deaths he thereby caused? Or why should it make any difference in the moral turpitude of the murderer's act, if a few of the crowd wore coats of mail in the first instance, or were protected by vaccination in the second?

The invisible messenger of death which is shot through the air in the former case, is not any more deadly to the stricken individual, than are the equally invisible germs of variola, as the graves of our 1,300 citizens dead from small-pox in 1881 testify. It is infinitely less dangerous to the public, because the leaden bullet ends its malevolent work with the human being it strikes down, whilst the vegetable missile may reproduce itself in its particular victim so as to originate a small-pox epidemic, and sacrifice in the community a hundred or a thousand lives.

The method for checking further dissemination of variola, which I have just advocated, is, of course, vastly inferior to that of establishing compulsory vaccination; yet I submit that whilst the latter plan infringes upon the personal rights of almost every one, the former curtails the liberties of a small minority only, and therefore, under our republican form of government, is far more likely to secure a majority vote in its favor, whether in the halls of legislation, or among the community at large.

—In irritable stomach complicating constipation, Prof. Da Costa ordered, at the clinic, oleum ricini floated on ice water, and said it would be retained.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Death from Rupture of an Aneurism of the Aorta.

Read by W. T. Taylor, M. D.

F. D. B., a letter-carrier, aged 26 years, came to see me on October 15, 1883, for a hoarseness; his voice at times being reduced to a whisper; a troublesome tickling cough, with an expectoration of frothy mucus; and pains through the left breast, extending sometimes down the left arm. He was slightly oppressed in his breathing after exertion, and generally debilitated.

He had not slept for several nights, and an apothecary had given him a chloral mixture, which did not relieve him, but "produced strange feelings and uncomfortable dreams," so that he would take no more of it.

On examining his throat I found a bifurcated uvula with the right branch much elongated; this was clipped off, relieving somewhat his tickling cough. There was slight dullness under the left clavicle, with some mucous rales, although the respiration generally was vesicular. The heart-sounds seemed distinct, but feeble, and the circulation was regular. His temperature was normal.

The mist. glycyrr. comp. with ammon. murias. was given to him for his cough and hoarseness. Tinct. iodine was applied externally to his throat and under the left clavicle, and the painful parts were bathed with linim. chloroform.

He was ordered to drink milk freely, to take beef-tea and easily-digested food.

For his insomnia I gave him a tablespoonful at bedtime of the following:

R.	Ammon. bromid.,	3j.
	Elix ammon. val.	
	Liq. morph. sulph.,	āā 3j.
M.		

This, however, only caused temporary rest, and had to be repeated frequently.

On October 26, as the hoarseness and cough still remained, I gave him some cod-liver oil and lactophosphate of lime, as a restorative, although I

did not consider him tuberculous, for there was no hereditary tendency to phthisis in his family, and he was well developed physically.

I advised him to go out on pleasant days, but not to tire himself with long walks, fully expecting that in a few weeks he would be able to resume his occupation.

The pains which affected his breast and left arm began to extend to the back, between the shoulder and up to the occiput, and became so violent that they could be only partially relieved by bathing with laudanum and chloroform liniment, and the internal use of anodynes.

On November 1, accompanied by his wife, he went to a bathing establishment to take a Russian bath, which some person had advised as being a positive cure for rheumatism. Arriving at the place he disrobed himself, preparatory to being bathed, when, on giving a slight cough, he raised some blood, which the attendant perceiving, he was advised to dress again. This he did partially, but in a few minutes such large quantities of blood issued from his mouth that Dr. Benj. Lee, who was in the building, was summoned to his relief.

The hemorrhage, however, was so excessive that he died in a few minutes.

An autopsy was made, the next day, by Drs. R. B. Cruice and Alexander, which revealed a rupture of an aneurism of the aorta at the intersection with the left carotid artery, which had opened into the trachea. The heart was of normal size, but its muscular fibres were very firm and large; the pericardium was distended with serum. There was some congestion in the upper part of the left lung, and some adhesions about the aneurism; but no tubercle was seen. The liver and other organs were healthy.

The pressure of this aneurism upon the trachea was the cause of his hoarseness and cough; but being behind the lung, I did not hear the aneurismal thrill, and, therefore, was entirely ignorant of the disease until it was revealed by the autopsy.

EDITORIAL DEPARTMENT.

PERISCOPE.

Probable Progressive Hemorrhage into Bowel, Depending on General Disorganization of the Blood.

Dr. R. M. Hodges reports this case in the *Boston M. and S. Jour.*, December 27, 1883:

Mrs. —, aged twenty-eight, mother of two children, and who, though never robust, had been in better health than usual during the past winter. Dr. Hodges was asked to see her at his convenience, as she was not feeling very well, although out and about as usual. At his first approach to her bedside, he was struck by the extreme lividity of her countenance, which reminded him of cholera cases. The tongue and fauces even were black, but the throat presented

nothing otherwise unnatural; the pulse was good; breathing quiet and calm; auscultation and percussion normal. No local cause for the condition could be detected, and there was no explanation of the appearance presented by the patient to be derived from her previous history. The only complaint made was of an annoying pain when, as she said, she hiccuped; the "hiccup" being in reality the eructation (in a very moderate degree) of gas from the stomach. An hour later attention was called to the patient's urine. But little had been passed during the night, and the specimen shown was less than half an ounce, and black like that in cases of carbolic acid poisoning. It was examined by Dr. E. S. Wood in less than an hour after it was passed, and contained one-fourth per cent. albumen, numerous brown,

granular casts, and much blood; the specific gravity being 1012. This suggested acute nephritis, and dropsy was expected, but it never came. In the afternoon there was a large, black, tarry dejection, not seen except by the nurse. Dr. M. Wyman, of Cambridge, visited the patient in consultation on the first day of her sickness.

The urine of the second day, also examined by Dr. Wood, contained no blood, but an immense amount of blood-pigment in solution, and a large quantity of serum albumen. Otherwise the same general characters remained. The patient's symptoms were unchanged, though the lividity had diminished. There was occasional nausea. She had one loose black dejection. There was considerable thirst, and simple food was relished. Dr. Wyman again saw the patient in consultation.

On the third day the urine regained its natural color, and the crystals of hæmatin disappeared. But one granular cast was found in a careful examination of five slides. The amount of albumen had, however, increased. The patient complained of severe headache, as well as pains about her waist, first on one side, then on the other, but they were never severe, nor was their nature comprehensible. Her color continued to improve, and she took milk, beef tea, jelly, and champagne, with much satisfaction. She had one dejection similar to that of the day before. Her intelligence and cheerfulness were not disturbed.

On the fourth and fifth days there were ten black and bloody dejections, some of them mixed with a good deal of transparent mucus, for which ergot and bismuth were given, and with apparent success, so far as the evacuations were concerned. The general condition continued about the same, and on each of these days she took and relished a chop, and some broiled chicken.

At the end of the fifth day she began to have dyspnoea and rapid breathing, and was restless during the night. This condition was first seen by the speaker on the morning of the sixth day, when the complexion had become sallow and the lips pallid. An eighth of a grain of morphia had been given the evening before, but this was thought to have nothing to do with the disturbed breathing, as she had taken it on other occasions without any unpleasant effect. The respiratory and cardiac sounds continued perfectly good, and at her solicitation the patient was placed in a chair for an hour at noon as a relief to the restlessness and dyspnoea. In the afternoon some slight râles were detected in the *front* of the chest, the respiration and percussion being elsewhere natural; the pulse fell from the seventies into the sixties, the heart sounds grew faint, the temperature went below normal, weakness increased, and death occurred at night. Dr. Wyman again saw the patient on this day.

At no time during the patient's illness did the amount of urine passed in twenty-four hours exceed two ounces. The temperature never rose above 98° F. She had very fair sleep at night, until that of the fifth day. There was never any somnolency or delirium, or any abatement of her cheerfulness and intelligence, until the afternoon before her death. The increasing pallor, together with the other symptoms which have been narrated, suggested that the fatal result was due to a progressive hæmorrhage into the bowel, appar-

ently owing to some general disorganization of the blood itself. There were no purpuric spots. Careful inquiry failed to obtain anterior evidence of any chronic renal symptoms, or other organic affection, or of any possible and recent drug poisoning. The patient had been frequently under the care of Dr. Hodges.

The treatment pursued was stimulating, supporting, anodyne, and expectant. Packing with blankets wrung out in hot water, and counter-irritation with mustard, were resorted to for the suppression of urine.

There was no autopsy.

The Influence of Iodoform on Body Weight in Phthisis.

Dr. A. Ransome thus writes in the *Brit. Med. Jour.*, January 5, 1884:

About a year ago, iodoform was introduced to the English medical public, mainly by Dr. Dreschfeld, as a drug likely to be of service in the treatment of phthisis, when used internally and by means of inhalation. I determined to give it a trial. At first I met with some disappointment; many persons, especially women, were unable to take it in consequence of the nausea and disturbance of the digestive organs that it caused. However, I still persevered, and gave it in the form of a pill, a grain and a half three times a day, to all the cases of phthisis who could take it. Shortly afterwards, at the suggestion of Dr. Marsh, I combined it with two grains of croton-chloral, and found that it was then much better borne by the patients, both male and female. Iodine and iodoform inhalations were also prescribed as a general test of its influence upon the disease. The weight of the patients was recorded for some little time before its use, and after its administration.

It seemed better to make no selection of cases, and it was given at all stages of the disease; and as patients seldom presented themselves in the incipient stage, the largest number of cases were in the more advanced stages of phthisis. The drug in several cases was stopped for various causes, and again recommenced.

Owing to the causes that I have mentioned, there are only 21 complete cases recorded at the present time. Of these, 4 were in the first, 5 in the second, and 12 in the third stage of the disease.

Of the 4 cases in the first stage, 3 appear to have received benefit; one (R. Jones) gained 2½ pounds in three weeks, and maintained her position for at least six weeks afterwards; another (S. Menzies) gained 2 lbs. in about one month, and although she lost weight somewhat on discontinuing the drug, she regained it again when the pills were recommenced. A third case (E. Lancell) gained 11 pounds in four months, and was then lost sight of. The fourth (M. Clevorty) lost weight on the whole to the extent of 8 pounds in three months.

Of the 5 cases in the second stage of the disease, No. 1 (McMillen) was losing weight rapidly when he commenced the treatment, at the rate of 3 pounds in a fortnight; he then gained 1 pound in the same space of time; lost weight on discontinuing the drug, gained again slightly on its recommencement, lost ground a third time on its omis-

sion, and entered on the third stage in about three months from the beginning of the treatment; but after again taking iodoform for several weeks, he improved and regained his former weight.

No 2 (Ross) also took the drug intermittently; he gained $2\frac{1}{2}$ pounds in ten days after first taking it; but after this it seemed to have little influence in arresting his downward course.

No. 3 (Brackenridge) presented a similar history, except that, in spite of sundry alternations of weight, he had on the whole gained somewhat in the course of seven months' treatment, during which time he had only omitted the iodoform for about three weeks.

No. 4 (Lockett) was a case of chronic pneumonia, which developed into phthisis after a lapse of four months. He was losing weight rapidly when he commenced the iodoform pills; but since then he has gradually improved both in weight and in the condition of the lungs.

No. 5 (Matthews) has only been a short time under treatment; but he has gained $3\frac{1}{2}$ pounds in the first fortnight.

Of the 12 cases in the third stage of the complaint, 2 (Burns and Burke) have distinctly gained weight since taking iodoform. Six, after sundry variations, remain approximately at the same weight, several after six or eight months of the treatment. The remaining 4 have all diminished in weight, with more or less rapidity. It is, however, remarkable that, even in these advanced cases, there is often a temporary rise for a short time after commencing to take the iodoform. Thus I note that, after a total number of 35 times of such administration, there were 28 periods in which there was an increase of weight, and only 7 in which the loss of weight continued without intermission.

From a review of all the cases, I am inclined, therefore, to attribute to iodoform some slight improvement, even in cases in which it was manifestly hopeless to expect cure; and I think that, in the earlier stages of the disease, it is decidedly worthy of further trial.

January 2, 1884. Since the above observations were made (August, 1883), the same treatment has been pursued in many other cases presenting themselves at the hospital, with very similar results.

Irritation of the Sexual Apparatus as an Etiological Factor in the Production of Nasal Disease.

Before the Baltimore Academy of Medicine, (*Maryland Med. Jour.*, January 26, 1884) Dr. Mackenzie first called attention to the early recognition of the relationship between overindulgence of the sexual powers and morbid conditions of the eye, ear and throat, by references to the medical writings of the ancients and quotations from the Latin classics. He had been unable to find any communication on the special part which such over-indulgence exerts in the production of nasal disease, in the literature of ancient or modern times.

To render the relationship between irritation of the sexual apparatus and nasal disease more intelligible, the anatomical structure of the nasal erectile tissue was explained, and the reflex and the *ab extra* influences which prove its erection.

Dr. M. believes that this tissue is especially concerned in the evolution of the many curious reflex phenomena observed in connection with nasal affections, and considers that the changes which it undergoes lie at the foundation of nasal pathology.

The physiological relationship existing between certain portions of the reproductive tract and the nasal erectile tissue appears (1) from the changes which the author has observed in the latter during the menstrual period. These consist either in simple engorgement, which may be uni- or bilateral, or may be associated with various reflex acts, such as coughing, sneezing, etc. The headache which occurs at the menstrual epoch may in some cases be due to the erection of this tissue; (2) from the presence of vicarious menstruation; (3) from the well-known sympathy between the erectile portion of the generative tract and other erectile organs of the body; (4) from the occasional dependence of phenomena referable to the nose during sexual excitement either from the erethism from amorous contact or during the consummation of the act of coition. Dr. M. believes that the congestion and consequent irritation of the nasal sensitive area thus brought about furnishes the explanation of the sneezing which has been observed during the performance of the latter; (5) from the occasional dependence of affections of the genito-urinary tract upon affections of the nasal passages; (6) from the connection between the sense of smell and erethism of the reproductive organs exhibited in the lower animals, and in those individuals whose passions are aroused by certain odors that emanate from the person of the opposite sex. From these facts, it is *a priori*, probable, that when carried to an excess, stimulation of the generative organs, from excessive use or disease, may not only become a factor in the production of congestive and transient inflammation of the nasal membrane, and especially of its cavernous tissue; but also become the starting point of chronic inflammatory changes in that structure. Dr. M. gave the following data, bearing on the subject from his personal observation in hospital and private practice: (1) nasal disease is, in a fair proportion of women, greatly aggravated at the menstrual period, and cases occur where the disease only makes its appearance at that time; (2) the discharge from nasal catarrh occasionally becomes offensive at the menstrual epoch, losing its disagreeable character with the decline of the ovarian excitement; (3) in ozena, the factor is much more pronounced during menstruation; (4) excessive indulgence in venery has a tendency to initiate inflammation of the nasal membrane, or to aggravate existing disease of that structure; (5) the same is true in regard to the confirmed habit of masturbation; (6) cases of nasal disease occasionally come under observation which are relieved upon the recognition and appropriate treatment of disease of the generative apparatus.

Dr. Mackenzie thinks that the above facts encourage the belief that irritation of the sexual apparatus may become a not inconspicuous etiological factor in the production of nasal disease. Whether this result from reflex action, pure and simple, as, for example, by virtue of the existence of correlated areas in the nose and reproductive

system, or as the sequel of an excitement in which several or all of the erectile structures of the body participate, the starting point of the nasal disease is in all probability the repeated stimulation and congestion of the turbinated tissue of the nose; and it is furthermore highly probable that morbid states of the latter may react upon certain portions of the generative tract.

The Direct Treatment of Spinal Caries.

The Med. Times and Gaz., January 12, 1884, says:

Good service was rendered to the subject of spinal caries, by the gauntlet which Mr. Treves threw down a few evenings ago at the Medico-Chirurgical Society. "Rien n'est sacré pour un sapeur" is a saying which will shortly be applicable to our modern surgeon, in that there will soon be few regions of the body which will be safe from his prying eyes, and his all-invading knife and fingers.

Spinal caries has long been one of the most troublesome and least satisfactory of those diseases which the surgeon has to treat, not only on account of its great inaccessibility, but also on account of the great extent over which it may and usually does spread. Moreover, the anatomical characters of the bones affected, viz., their sponginess and great vascularity, lend additional importance to any inflammatory process which may be set up. Expectation, therefore, ran high when the above paper was first announced, in which the direct treatment of spinal caries was to be advocated and backed up by the record of three cases in which the operation had been performed.

The outcome of the discussion, though of very great interest and importance, has not quite borne out what the title of the paper first promised, viz., direct treatment of carious bone. But, as a means of examining the lumbar vertebræ, of reaching any possible necrosed and loose fragments of bone, and more especially as a means of opening, draining, and treating abscess of this region on the most approved principles, the operation promises to be of great service.

Mr. Savory, in his usual masterly style, pointed out all the dangers which would attend the *satisfactory* treatment of spinal caries, by referring to the difficulties and contrasting treatment of tarsal caries, even since the use of Esmarch's bandage had so much facilitated this proceeding. Caries, said Mr. Savory, is not a primary condition, but is preceded by inflammatory changes; and, unless the whole of the diseased tissue could be removed, the operation might prove worse than useless. Moreover, there are other dangers which were not alluded to. In young persons, the subjects of this disease—mostly of a scrofulous or tubercular type—there is always the danger of setting up an acute tubercular process, which is rapidly fatal, either in the form of meningitis or of general tuberculosis. And lastly, the removal of carious bone will not always save life, even should the local mischief be cured, as one of the recorded cases proved.

Nevertheless, the proposed operation was carefully worked out on strictly anatomical lines, and its feasibility was demonstrated. For the removal of pus, it can hardly fail to be of the greatest service.

The only difficulty will be to recognize pus early, and this is certainly not an easy matter. One of the speakers referred to the relative frequency of pus collections in disease of the lumbar and lumbar sacral regions, as compared with other regions of the spine, and this will, in a measure, justify an exploratory incision when the disease is situated low down and the presence of pus suspected. We shall probably not have to wait very long for further records of this operation and can only hope that "the mania" for new operations, to which some speakers referred, will not outweigh that discretion which, in a surgeon especially, is even better than valour.

A Case of Gangrene of Extremities from Emboli.

Dr. O'Brien reports this case in the *Med. Age*: "I was called to attend a negro woman, æt. 32, in her second confinement. The labor was natural, and, as is the custom with these people, she was about the house in a week or ten days, feeling perfectly well. About four weeks after I was called again. The woman had awakened in the morning and found the right foot numb and cold. It was "dead," as she expressed it. Otherwise she felt as well as usual. I ordered the foot elevated and the limb wrapped in cotton batting. In a few days the skin began to slough, and the line of demarcation formed at the junction of the upper and middle third. Supporting treatment was given, and carbolic acid used on the gangrenous member. Her appetite was good, and she suffered no pain, resting well at night. She was cheerful and worked with her needle as she sat in her chair during the day. About six weeks from the commencement of the case, and while nature was doing such good work at the line of demarcation on the right limb, the left foot suddenly became cold, and gangrene was found present. A line of demarcation formed in the left some two inches lower than in the right limb. The woman's appetite remained good, and she rested good, suffering little or no pain. Knowing the case would be fatal, I watched it closely. On the tenth week both arms suddenly became cold, and I had a case of gangrene in both lower and both upper extremities. The woman now had considerable distress in breathing, and a rapid irregular action of the heart. On the fourteenth week pneumonia set in, and the case ended in forty-eight hours.

"Autopsy eight hours after death.—Post-mortem rigidity absent; body emaciated; line of demarcation well formed in right leg, in the left distinct. Uterus was removed and carefully examined. There was no evidence of any inflammatory trouble present. The changes following pregnancy had occurred naturally. The heart was enlarged and the valves studded with vegetations. The heart substance was soft and friable. The lungs were engorged and the pleura contained a quantity of fluid, which gushed out as the chest was opened. The femoral arteries were filled with clots, and the vessels occluded in the popliteal space by inflammation. The axillary arteries were filled with clots extending to where the vessel passes over the first rib. This woman had never had rheumatism or any serious illness; had never suffered any distress referable to the heart; on the contrary, had always enjoyed the best

health previous to her last confinement. Such was the history given me.

"Professor Blackman, of Cincinnati, in a pamphlet written by him some years ago, reports several cases of puerperal gangrene almost identical with this of mine. It is true this woman suffered cardiac distress during her illness. She had a rapid pulse and a blowing sound over the left heart. Evidently the trouble was from the detachment of vegetations in the left heart, and they of such size as to occlude the axillary and femoral arteries. But there is an apparent absence of any heart trouble until after confinement, so the puerperal state must have, by blood changes, developed the organic trouble in the heart.

"I made a post-mortem in a case of sudden death in a brother of this woman, æt. 28. The heart was as large as a bullock's, and the valves and chordæ tendinæ covered with vegetations; the heart substance friable. This man was a common laborer, but in spite of his every-day work, had never suffered any distress or symptom referable to the heart; in fact, he had never been sick.

Congenital Malformation; Urethra Opening into Vagina.

Dr. W. D. Wilkes reports this case in the *Med. Times and Gaz.*, December 22, 1883:

A private patient lately died in her ninetieth year; she had been a widow forty-two years, and had never borne a child.

Of late years I ascertained that she had frequently difficulty in passing urine. With this exception, an accident in 1880 (broken ribs and contusions of face and neck), she had always been well. In October, 1881, I was consulted for cystitis and retention of urine. On examination, I found a congenital absence of the orifice of the urethra in front at its usual place, and only a very contracted orifice of the vagina, barely admitting a probe, through which the urine could not pass at all.

Under chloroform I enlarged this opening, and afterwards small phosphatic calculi began to pass at intervals, formed in the bladder, forced by it into the vagina, and escaping from it with the urine. The calculi generally required removal, and at times quite stopped the orifice, and had to be broken up before extraction. The urine always contained blood, often in clots, and much muco-purulent matter. No probing of the vagina could detect the opening of the urethra into its roof, and the bladder could not be sounded. Neither sponge-tents nor drainage-tube could be borne in the vagina, and there was a refusal to submit to any kind of operation, such as exploratory lithotomy, or introduction of a drainage-tube from the front, for the cystitis and more easy escape of urine. Her sufferings when wanting to empty the bladder were very great—every hour or so during the night, but less often in the daytime. She also refused all medicines, and sedatives had to be given unknown to her.

I was allowed after her death to make a local examination. The bladder, thickened, contracted, and very vascular, contained fragments of phosphatic calculi, blood-stained and mixed with

muco-pus. A probe could be passed from the base of the bladder into the vagina, and onwards through its orifice, showing a congenital vesico-vaginal urethra. This opened into the upper wall of the vagina about one inch and a half from its orifice. The uterus was atrophied, and had a globular deposit of bone at the side of its anterior wall. Two or three similar deposits were forming at the fundus. The vagina was much dilated, forming as it were a second bladder; its orifice was much contracted, and had become an organic stricture, similar to that in a male urethra.

I have never been able to meet with a description of such malformation. I suppose that until the vaginal orifice contracted, no suspicion of it existed, as there had never previously been any examination of the parts. I hardly know what surgery could have done. It is doubtful whether it would have been possible to close what was the natural urethra, and establish an artificial one in its usual place. The bone pipe of an ounce ball-syringe was passed daily or oftener, and the vagina syringed out. This kept the orifice from further contraction, and favored the escape of the calculi. Had the patient allowed one, the best treatment would have been a free dilatation of the orifice to admit the finger, when the situation of the urethra might have been detected, and the opinion formed during her life confirmed; whilst the urine would have had an easy escape, and much suffering been relieved.

Sterility and Conception.

Rusconi, in an article of great interest (*Gazz. degli Ospitali*, October 24, 1883), discusses one or two aspects of these subjects. Having drawn a distinction between infecundity, an irremediable condition, and sterility, a condition that may perhaps be removed, he goes on to divide this last (sterility) into two forms, mechanical and mechanico-pathological. In the mechanical form, the entrance of the semen into the body of the uterus is prevented. Mechanico-pathological sterility occurs in cases of uterine catarrh and other ailments, where, even if the semen succeed in reaching the cavity of the womb, it is only after it has been damaged chemically, and consequently is no longer active. The time and the manner of conception are then examined. The fact that fecundation may occur midway between two menstrual periods has given rise to four different theories: 1, that ovulation is not periodical in woman; 2, that the ovum may reach maturity during the excitement of sexual congress; 3, that the ovum may remain fertilizable in the uterus or oviduct; 4, that the semen retains its activity in the uterus until the ovum appears.

In regard to the accelerated maturation of the ovum from sexual excitement, is mentioned the fact that girls who have never menstruated do so shortly after their first embrace. Then the author combats the old opinion that spermatozoa can make their way into the uterine cavity if they have been already abandoned only in the vagina. Pallen, Fraer, Rouget, and Kolbert, have all shown the falsity of such a doctrine. Experiments on the dead body are then related, which seem to put it beyond doubt that semen can enter the uterus only at the time of coition. The

rectum, bladder, and superficial pelvic fascia having been removed, the veins of the genital organs were injected. The uterus rose in the pelvis, the normal curvature diminished, the anterior wall became convex, the diameter of the cervix increased, and its external orifice dilated. At the time of the greatest engorgement of the vessels, the os uteri corresponds exactly to the centre of insertion of the vagina. Additional facts are drawn from clinical observation. In some cases of completely prolapsed womb, where irritation of the clitoris gives rise to insupportable orgasm, the mouth of the organ may be observed to open. Again, Pallen observed a case where the introduction of a speculum brought on the orgasm, during which the orifices could plainly be seen to dilate. Too great an intensity of the orgasm, however, is calculated to prevent conception, owing to excess of glandular secretions. As soon as the erection of the uterus is over, the mouth closes and the semen remains perfectly shut in. Hence injections used after coitus to prevent conception are without effect; unless, indeed, uterine contraction provoked by the cold water expel the contents. Injections of this kind, however, readily give rise to uterine catarrh and so cause sterility. In the author's opinion, the cure of sterility is not easily accomplished. Occasionally the results are fortunate; most frequently, however, there are insuperable obstacles. A caution is given, finally, as to the possibility of the failure being on the man's side. He has known a lady to be three years under treatment for sterility, the incapacity being really due to her husband, owing to the absence of spermatozoa in the seminal fluid.

Suppurating Hydatid of Abdomen: Free Incision; Recovery.

Dr. Felix Jones reports this case in the *Lancet*, December 15, 1883:

"On August 1, 1881, I was called to see R. T., aged fourteen, a slenderly-made youth, who had previously enjoyed good health. The history of the case was that he had taken cold about a week before; this was followed by rigors and tenderness over the abdomen, with gradual enlargement. No vomiting, bowels constipated, urine clear and scanty. Temperature normal. Circumference of abdomen, 30½ inches. Well-marked thrill; dullness on percussion over front and sides, as if the intestines were pushed upwards away from the abdominal wall.

"August 4. Circumference of abdomen 31 inches. Vomiting everything. Great pain in the back. Temperature normal.

"5th. Paracentesis was performed in two places in the linea alba below umbilicus, and four quarts and a half of thick creamy pus were evacuated. From this time all bad symptoms ceased, and the boy made a good recovery.

"In April, 1883, I was called to see the same patient, whose abdomen was again distending slowly and uniformly, more in front than at the sides, and simulating in appearance an ovarian tumor. No abdominal tenderness.

"May 10. As distension had increased rapidly, and the patient was much emaciated, I aspirated the abdomen in the linea alba, but no fluid came away. I tried a small trocar with the same re-

sult, the canula being blocked up with gelatinous material. The following day a large-sized trocar was used under chloroform, and about three quarts of creamy pus were removed. The swelling subsided, but there was great pain in the back. Ordered one-grain opium pill every four hours. In a few days the tumor commenced to refill.

"24th. While in the act of defecating, a quantity of pus and small hydatid cysts were expelled through the opening in the abdomen.

"June 1. Chloroform having been administered, I made an opening one and a half inches in length in the linea alba, an inch below the umbilicus, and opened the tumor; a large quantity of pus, hydatid fluid, and cysts, varying in size from a cocoanut downwards, were expelled. I passed my finger into the cavity to remove more cysts and to explore its direction; I found it apparently connected with the pelvis. The cavity was then washed out with a weak solution of carbolic acid, and a large-sized drainage-tube inserted. Ordered one-grain opium pill every four hours, and a liberal diet of wine, milk, beef-tea, etc. The patient appeared very prostrate after the operation. The cavity was washed out twice daily, iodine lotion being substituted for carbolic, and several more small cysts came away. The temperature for the next week only once rose over 100°. An epidemic of scarlatina existed in the town at that time, and unfortunately my patient was seized with it; but, notwithstanding that serious complication, he pulled through satisfactorily, and on July 18, when desquamation had ceased, was able to go about. On October 18, I saw him again, and he looked quite rosy, and was in excellent health.

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—A small 12mo. volume of 68 pages, entitled "Hand-book of Eclampsia, or Notes and Cases of Puerperal Convulsions," has been prepared by five physicians of Chester county, Pa., Drs. E. Michener, J. H. Stubbs, B. Thompson, R. B. Ewing, and S. Stebbins. (F. A. Davis, Philadelphia. Price, 75 cents.) It relates the details of 44 cases in country practice, and is written with the object of showing that the correct treatment of this complication is to bleed promptly, freely, and from a large orifice. The cases were ably analyzed, and this plea for venesection should receive the most attentive consideration from obstetricians.

—In a reprint before us, Dr. E. W. Jenks, of Chicago, recites two cases of operation for fistula in ano "by a method similar to that for a torn perineum." The details are carefully stated, and the plan certainly promises favorably.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,

ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D., }
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

THE LEGAL RIGHTS OF BOARDS OF HEALTH.

An important decision has been pronounced by the Supreme Court of the State of Louisiana on a subject which touches a class of professional men in all the maritime States.

An act of the General Assembly of Louisiana provides that every vessel which enters the port of New Orleans shall be inspected as to its sanitary condition by the resident physician at the quarantine station, for which he is to receive a fee fixed by the law, and not in any case excessive. The payment of this fee was refused by the Morgan Steamship Company, on the grounds that its exaction was unconstitutional, that the inspection was no benefit to them, but rather a hindrance, that it was a forced contribution, and hence against the policy of a free government, and on some minor technical grounds.

The lower court gave a decision in favor of the steamship company, but on the appeal the Supreme Court reversed the decision, and ruled in favor of the Board of Health. The grounds on which it did so are so pertinent to a series of similar questions touching the duties of physicians to State and municipal matters that we shall make a pretty long extract from the opinion. After ruling out as irrelevant various minor matters, the opinion proceeds:

This elimination leaves open, on this branch of the case, the solitary question, whether the fees and charges here involved are duties in the sense of the constitution? It is the well-established jurisprudence that there are many forced contributions which government may exact from persons and property which are not considered as taxes, duties or imposts, within the meaning or control of constitutional restrictions upon the power to levy the latter. Such are contributions provided for the construction of public works for the advantage of particular districts, like levees, drainage, pavements, etc., levied on property with reference to the supposed benefits derived by the property from the works; contributions provided to defray the expenses of building bridges, erecting causeways, or removing obstructions in a water-course, and like the light duty paid by all nations to the Danes, to be paid by such individuals only who enjoy the advantage; and fees or charges for services lawfully rendered, like wharfage, pilotage

and port-warden fees, to be paid by those who receive the services. *State vs. Navigation Co.*, 11 Mart. O. S., 324; *Crowley vs. Copley*, 2 Ann., 329; *Lafayette vs. Orphan Asylum*, 4 Ann., 1; etc.

As to the second point, that the services are forced and not voluntary, the reliance placed upon the decisions of the Supreme Court of the United States in the wharfrage and port-warden cases seems not well founded. In those cases there was no legal duty imposed on vessels to land at the wharves or to receive the services of the port-wardens. They had the perfect right to decline these benefits and services, and the court properly held that a State law exacting contributions for them, whether used or not, was unconstitutional. But had it been the legal duty of vessels to land at a particular place in the port of New Orleans, and had the city provided expensive wharves at such places, is it supposed that she would not have had the right to exact compensation for the facilities thus afforded, although vessels landing at the port would have no option as to accepting the use of them?

Finally, it is claimed that the services rendered under these quarantine regulations are for the benefit of the people of the city and State, and not for that of the vessel. No doubt that is true. It is equally true that the object of the city in building wharves was to benefit its own people, trade and commerce. We deem it unnecessary to consider more at length the objections which have been forcibly urged against the theory that the services in question are rendered to the vessel in such a manner as to justify the exaction of compensation therefor. What we have said sufficiently expresses our views on the subject; and while the question is not free from difficulty, even to our own minds, we are confirmed in our course by the reflection that it leaves the avenue open for correction of any error which we may commit, by appeal to the Supreme Court of the United States; whereas if we should err in the opposite direction, the defendants would not be entitled to that remedy.

In the first of the cases above quoted, Chief Justice Martin said that the words, "impost, tax, or duty," as used in the constitution or laws, must be confined to the idea which they commonly and ordinarily present to the mind: exaction to fill the public coffers, for the payment of the debt and the promotion of the general welfare of the country—and not to contributions as the supposed equivalent of benefits conferred or services rendered, like those above indicated.

It is apparent from the face of the laws here attacked, that the fees and charges complained of are demanded as compensation for labor performed, expenses incurred, and services rendered, directly in connection with the vessels, the necessity for which arises solely from the fact that such vessels, in the exercise of an undoubted right, yet voluntarily in pursuit of their own interests, choose to seek the port of New Orleans, well knowing that they cannot enter said port without first being inspected, and, if necessary, purified, in conformity with laws to that extent unquestionably valid. Can it be said that the rendition of these services, by virtue of which alone the vessel is enabled, lawfully, to proceed to her destined port, is not a service to the vessel?

It is said that it cannot be considered as a service, because the vessel does not regard it as such, but rather as a burden, and because she does not voluntarily seek or avail herself of it. As to the first point, the question would seem to be, not whether the vessel regards it as a service, but whether it is a service, and whether she ought to regard it as such. It seems the plainest development of the primal duty, *sic utere tuo, ut alterum non laedere*, that a vessel should seek and desire the performance of services the object of which is to prevent the chance of her spreading disease and pestilence amongst large populations. She is under the plain obligation, moral as well as legal, to do everything to avoid such risk; and the service which enables her to perform this obligation would seem to be a service to her.

The broad proposition of plaintiff, that in the exercise of the right to establish quarantine systems, the States are bound to bear all the expense thereof, and cannot throw the burden, in any manner or to any extent, upon commerce, has certainly not yet received the indorsement of the Supreme Court of the United States.

This final "broad proposition" in reality underlies the whole question at issue, and its clear enunciation and final decision is absolutely necessary to a comprehensive system of national sanitation.

The common sense view of the case clearly is that every man and company who are engaged in a business in any way liable to injure the public health, should be made to pay a sufficient sum to the public treasury to protect the public against the injury liable to result to it from the business.

THE PRESENT POSITION OF THE GERM THEORY.

The rapid strides which pathological histology is making are gradually overtaking the elusive "cause of disease." Hunted down to the lowest forms of animal and vegetable organisms, it may now be said to have been driven out of them and into a smaller field; in which we are close upon its tracks.

Not that the relations of germs, bacteria and bacilli, are no longer of importance; they are of great importance, but they are no longer directly causal, only accessory to the true causes, as these are now understood.

To explain this it may be stated that the study of the life-histories of the lowest germs has shown that while they are present in disease, they are also in health; that they may be cultivated and inoculated without producing disease, although generally they may produce this result; and that noxious and innoxious varieties present no objective differences, and are therefore probably identical, and act differently not because they are of different species, but because they are under different conditions.

Hence, it has long been suspected that the bacilli, etc., are rather the carriers of disease than its direct producers; and the inquiry has been directed toward what it is that they carry. Is it a chemical poison, or what?

The question now seems on the verge of a reply to the effect that it is some semi-organized ferment, something of the same nature as pepsin, pancreatin, etc., but differing from these normal and health-giving ferments, in that its action is destructive or injurious to the living animal cells, impeding their functions, or attacking their integrity—resembling, therefore, the so-called *ptomaines*, and similar products of decomposition and putrefaction. In the living blood a fibrin-ferment may be rapidly liberated, which will deteriorate the blood-cells and lead to septicæmia.

The introduction and production of these ferments—which have not yet been isolated and studied in any large number—are very generally associated with germ-migration and reproduction, but not always; and there is strong evidence for

the belief that this is only one of several ways by which the healthy system becomes exposed to their action.

The immediate future of the study of the causes of disease lies in the separation of the coincident phenomena from the real cause, and in the identification of these semi-organized ferments. The field thus opened is even a more difficult one than that of microscopical life; it belongs to pathological chemistry, and the methods for its successful exploration have scarcely as yet been discovered; but we may rest confident that the attention given to this central point of medical science will not long remain unproductive of practical results.

STATISTICS OF ALCOHOLISM.

Some rather startling figures have been lately published by the Bureau of Statistics, showing the consumption within the United States of proof spirits, wine, and malt liquors. The following table exhibits the total quantity of each consumed, and the per capita consumption:

	Annual av'ge for 3 years ended June 30, 1878.	Annual av'ge for 3 years ended June 30, 1883.	Increase per cent.
Distilled spts., galls.,	57,111,982	73,641,727	28.94
Wine, " "	19,812,675	25,248,233	24.43
Malt liquors, " "	310,653,253	508,977,788	63.55
Total.....	387,577,910	606,967,738	56.60
Cons'n per cap. gals.	8.36	11.49	37.44

These figures can be put in a different way so as to show the relation of consumption in 1883 as compared with the average of the three years ended June 30, 1878:

	Annual av'ge for 3 years ended June 30, 1878.	Year ended June 30, 1883.	Per cent. Inc.
Distilled spts., galls.,	57,111,982	76,762,063	34.40
Wine, " "	19,812,675	25,885,492	30.65
Malt liquors, " "	310,653,253	555,375,654	77.81

Professor Elliott, of the Treasury Department, estimates the total population in 1883 at 54,163,000. Upon that basis we have a per capita consumption of 10.18 gallons of malt liquors, 1.42 gallons of distilled spirits, a fraction below a half gallon of wine.

We here see that in spite of temperance societies, and all the efforts of the prohibitionists, the consumption of all these varieties of intoxicating liquors has increased greatly, not only absolutely,

but also in proportion to the growth of the population. As a community, as a nation, we are more given to inebriate indulgence than we were five or six years ago.

This ominous fact may well lead to serious reflection. Have the measures heretofore adopted to check this pernicious habit been ill-adapted to the end? Would it not be better if the purely medical view of the cause of inebriety were more generally received? We leave these grave questions to the serious reflections of our readers.

THE COLLECTIVE INVESTIGATION OF DISEASE.

This movement has met with great success in England, and is, no doubt, destined to aid us greatly in our warfare with disease.

The committee having the matter in charge, decide upon a certain disease which they desire to have investigated, and they then send out circulars, containing questions about this particular disease, which they request the different physicians to whom they are sent to answer from their experience.

A similar movement is on foot in our own country, and we desire now to suggest a plan by which every physician can make himself a benefactor to the profession, and materially assist in increasing our acquaintance with the phenomena of disease. Let each man keep a careful record of all his cases, jotting down notes at the bedside, and amplifying them at his leisure at home.

If he does this, and at the end of three or six months reads over his cases, he will be sure to find, no matter how humdrum may be his practice, some phenomena in some cases that have never been described. If he will then write a short concise article detailing his experience, and send it to some medical journal for publication, he will thus add his quota to the collective investigation of disease.

NOTES AND COMMENTS.

Bromide of Ethyl and Nitro-glycerin.

From *Breslauer Arztl. Zeitsch.*, we learn that Professor O. Berger has found bromide of ethyl use-

ful, (1) In neuralgic conditions of the nerves of the face and head, in megrim, and in nervous headache and heaviness. The inhalation of twenty to forty drops of the remedy several times a day has lessened headache in cases where quinine, salicylic acid, caffeine, and guarana, had all proved useless; and in three cases of headache connected with cirrhosis of the kidney it was better than any other remedy. (2) In neurasthenia: it is here given in doses of from one to three grammes twice or thrice a day, if necessary. (3) In epilepsy: here it is of very little use, although Bourneville and D'Ollier considered it useful. They narcotized their patients daily for ten to twenty minutes with it, but when given in doses of one gramme daily by inhalation it is useless. It is besides expensive, and causes much depression. When inhaled before or during the epileptic attack, it only prevents or cuts it short in exceptional cases. (4) In hysteria it is of more use. The attack of hystero-epilepsy may sometimes be cut short by narcotizing with it for ten or fifteen minutes, eight to twelve grammes of the drug being required. When given in doses of a half gramme to two grammes by inhalation once or twice a day, it may avert a threatened attack of hystero-epilepsy. (5) In several cases of psychical excitation, the bromide of ethyl has proved serviceable. The author finds nitro-glycerin also useful in headache.

The Dangers of Nerve-stretching.

That this valuable procedure may sometimes prove dangerous, the following case, reported by Westphal in the *Charité Annalen*, gives evidence:

A man aged 31, suffering from paralysis of the lower extremities, with spasmodic phenomena (startings of the limbs, exaggeration of deep and superficial reflexes, disturbance of sensation), was submitted to the operation of stretching the right crural nerve. Immediately after the operation a transient loss of the knee-jerk was noted, with stiffness of the muscles of the right limb. But incontinence of urine and stools, with contracture of the flexor muscles and the appearance of a large slough at the site of the operation, also appeared and endured. The patient succumbed three years afterwards. At the autopsy the brain, the pons, and the medulla oblongata were found to have islets of degeneration; the cervical and dorsal segments of the cord were the seat of a diffuse degeneration, which attained its maximum in the middle part of the dorsal region; finally, the right half of the lumbar enlargement was sown through with numerous foci of degeneration,

which Westphal considered as in all probability produced by the laceration resulting from the stretching of the right sciatic nerve. The weight of the authority makes the case worth recording in regard to the possible dangers of nerve-stretching.

Rational Hydro-Therapeutics.

Dr. George Lucas Pardington contributes an article with this title to the *Practitioner*, January 1884, which contains the following practical suggestions. A course of drinking cold water plentifully between meals has a very good effect on patients who lead a sedentary life, and whose secretions are scanty and defective; the secretions become re-established and effete matters are carried away from the circulation; the tissue metamorphosis also is rendered more complete.

The free use of cold water is of especial use in gouty subjects; the blood is diluted, the quantity of urine increased, and the excess of uric acid is rendered more easy of removal.

The action of cold water on the stomach is that of a stimulant—provided always it be taken in moderate quantities—the cold acting on the peripheral terminations of the afferent fibres of the vagus as a stimulus, causing an increase in the flow of gastric juice, and fitting the stomach for the reception of food; the movements of the stomach are also increased, and so the digestive powers enhanced. If the quantity of water taken be too large, the stomach is distended, its movements impeded, the gastric juice diluted, and digestion much impeded.

A tumbler of cold water taken on an empty stomach on rising, rapidly stimulates the peristalsis of the intestinal tract, thereby assisting in the onward passage of feces; this well-known remedy is an excellent one in cases of habitual constipation.

Some Causes of Inflammation of the Brain in Children.

One by one the various ills that afflict humanity are being attributed to bad hygienic conditions, and now Dr. John Ward adduces strong evidence in the *Lancet*, January 19, 1884, that several cases of inflammation of the brain in children, which he has observed, were caused by defective drainage. He says:

"That morbid states of the brain may be due to a poisoned state of the blood, the frequency with which brain symptoms manifest themselves in the progress of zymotic diseases attests; and we may, I think, reasonably infer that associated in-

sanitary conditions, which so powerfully predispose the human system to the development of the class of diseases named, may be alike provocative of the other class now under consideration. Nor should we suppose that the delicate vaso-motor nervous system, whether apprized of depressing morbid influences, present in the atmosphere, through the digestive organs, the lungs, or more immediately by its own functional activity being affected, would be slow to convey, through the blood, or more directly, to the great cerebro-spinal nervous system, with which it is so closely associated, a sympathetic influence. A period of time devoted to the interests of official sanitary work has afforded ample opportunities for observation, which appear to confirm the views herein advanced as to the association of insanitary influences with the development of brain symptoms, for the most part in children."

Curious Congenital Malformation of the Sternocleido-mastoid Muscles.

Dr. N. O. D. Parks, of Ashton, R. I., sends the following curious history to the *Med. Record*:

"On October 18, I was called to a primipara who had been in labor since 4 a. m. the previous day, in charge of a midwife. I found the breech presenting, and delivered her of a boy, healthy in every respect save that he was tongue-tied, and presented what I at first took to be enlarged cervical glands. These I subsequently caused to be painted with colorless tincture of iodine. This had no effect whatever in dissipating the tumors. On closer examination I then found a single cartilaginous tumor occupying the site of the sternocleido-mastoid, as if that muscle had been converted into cartilage; the sternal end being much more prominent, and feeling hard and rigid, exactly like the trachea. It appears to give the child no trouble, and could be manipulated quite roughly without eliciting any cry or other sign of discomfort. When the child turns his head in the direction of the tumor, it seems to cause pain by pressure on the adjacent parts. I told the parents it was useless to make any further applications to it, and that it was better to leave it to nature. As this seems, to me at least, a unique case, you may think it worthy of record, and if you or any of your readers know of similar cases, might offer suggestions as to the probable cause and treatment, if any, of such abnormality."

Lobelia Inflata in Asthma.

The *Med. Record*, quoting from the *Bull. Gen. de Therap.*, says that Dr. Fournier has used lobelia

to a considerable extent in his practice for the past twenty years in cases of asthma, phthisis, and pulmonary congestion. He has not found very much advantage in its use in simple asthma; but in cardiac dyspnoea, in doses of fifteen to thirty minims of the tincture per diem, he has obtained good results as a rule. In suffocative attacks occurring in the later stages of phthisis, when all other remedies failed, this drug was often of the greatest service. It was given in a mixture of one-half drachm to eight ounces of water, a tablespoonful every hour. The author relates some cases of sudden dyspnoea occurring in the aged, in which lobelia seemed to be of the greatest value. These attacks occur very suddenly; the patients are asphyxiated and pulseless and seem to be on the point of death, and indeed the termination is usually fatal. Dr. Fournier regards them as due to congestion of the lungs from paralysis of the vaso-motor nerves. In congestion from other causes the influence of lobelia is slight.

Humane Blistering.

When we think how painful the results of blisters are to our patients, and yet how valuable they are, we will hail with pleasure the following suggestion of Dr. Samuel Stretton in the *Brit. Med. Jour.*, January 26, 1884:

In an illness about fifteen years ago, I myself suffered considerable distress following the application of a large blister (which, no doubt, was instrumental in saving my life); but since that time I have never directed a similar torture for others, though I obtain satisfactory results from the blistering process I do employ. I direct the surface requiring such counter-irritation to be well covered with annular blisters about the size of the human iris, cut from vesicating tissue with an ordinary gun-punch, the centre being extracted with a punch of small size. Once secured to the surface, and covered with cotton-wool and bandage, these blisters require no further attention. The discomfort created is so slight that I never meet with the slightest resistance to their application.

Ulcerous Typhoid Sore Throat.

Dr. E. Rapin (*Rev. de Therap.*, January 15, 1884,) thus formulates his experience:

1. Typhoid fever affects the throat more often than is generally supposed; in fact, the first symptom may be a sore throat of an ulcerous nature.

2. The ulcerations are superficial, rounded, or, more usually, oval, with a slightly elevated bor-

der, hard floor, ordinarily indolent, and generally situated on the anterior pillars of the fauces, and on their anterior face.

3. Their diagnosis is sometimes very difficult; it is only by frequent examination and attention to the general symptoms that they can be certainly recognized. These ulcers seem specially to affect the lymphatic system; the lesions of the lymphatic apparatus are identical with those found elsewhere in the course of typhoid fever.

4. Their development is due to the direct penetration of the typhoid germs into the follicles of the faucial region.

Cancer of the Rectum.

Prof. Trélat (*Rev. de Therap.*, Jan. 16, 1884), formulates the following propositions in reference to treatment:

1. Cancers of the rectum which do not cause accidents should be left alone.

2. Cancers of the very extremity of the rectum, or of the margin of the anus, should be extirpated.

3. Accidents should be treated as they arise, but palliative measures are to be avoided. In this respect, he is in accord with Prof. Verneuil, but opposed to many English surgeons.

4. When the finger can be passed beyond the cancerous mass, rectotomy should be performed, otherwise not; but a way of derivation should be made by lumbar colotomy or by forming an inguinal anus.

Neuralgia of a Labium.

In one of our English exchanges, Dr. J. Matthews Duncan says: "I have never seen any neuralgia more intense than that of the cord in the male. One case in a clergyman I can never forget, it was so very severe. In woman I have only seen it distinctly a few times. The worst case was that of a stout old lady liable to bronchitis and asthma. In her it came only occasionally, but when it did come it was so severe as to cause much alarm; the pain ran along the cord or rather the round ligament in the right inguinal canal, and was most severe in the corresponding labium. It was soothed by kind attention, hot bathing being generally used, sometimes anodyne applications to the skin."

The Micro-Organism of Gangrenous Septicæmia.

From a foreign exchange we learn that Messrs. Arloing and Chauveau communicated, in July last, to the Société des Sciences Médicales de Lyon, the results of their researches on gangrenous

septicæmia. They are of opinion that the disease is caused by a special bacillus, which they have found around the wounds and on the phlyctenæ. The bacillus has the form of a short rod, provided with one or two spores, and can be inoculated by injection. Tissues deprived of their vitality, or disorganized by hæmorrhage, are most favorable to its action and reproduction. When fresh, the bacillus can be destroyed by a temperature of 90° to 100° C.; but, after desiccation, a temperature of 120° C. is necessary. Sulphurous acid and a warm solution of carbolic acid (5 per cent.) are, after heat, the best means of destroying this micro-organism.

Spasmodic Winking.

How often do we see boys and girls, otherwise attractive, rendered unpleasant to themselves and to others by a constant winking or twitching of the eyelids, which is usually attributed to "nervousness," and the hope expressed that "they will outgrow it." In *Memorabilien*, Dr. Friedreich Betz relates the history of a boy, fourteen years of age, who had suffered for several years from a bilateral nictitating spasm of the eyelids. Several physicians had attempted to relieve him, but in vain. The boy was healthy, and his eyesight good. He had, however, very long eyelashes, and the edges of the lids were reddened. Betz performed epilation of numerous lashes above and below on both eyes. The treatment was immediately successful.

How to Create Good Feeling Between Teachers and Students.

The number of professors at the German Universities is so great, and the reverence of the students so enthusiastic, that the celebration of some form of jubilee or another is a never-ending occurrence. That of Professor DuBois-Reymond has only just finished, amidst great enthusiasm, and now preparations are being made to commemorate the fact that just twenty-five years have elapsed since the renowned clinical teacher, Professor Frerichs, accepted the call from Breslau to Berlin. These celebrations are very commendable, as they serve to keep up a good feeling between the professors and the students.

Hydrastis Canadensis in Painful Menstruation.

In one of the recent numbers of the *Archiv. für Gynäkologie*, Prof. Schatz calls the attention of his colleagues to the value of tincture of hydrastis in many cases of painful menstruation, which hitherto have been supposed to need operative inter-

ference. The hydrastis contracts the vessels and lessens the genital congestion. Often by its use the pain attending the menstrual epoch is diminished or wholly removed. The preparation which Prof. Schatz uses and recommends is the fluid extract, as prepared by Messrs. Parke, Davis & Co., of Detroit, Michigan.

Cases of Trichinosis.

A report of sixteen cases of trichinosis from the Cologne hospital has been made by Dr. Leichtenstern. The more severe cases were characterized by high continued fever, the temperature reaching 106°-109°, which is attributed to the myositis. The disease lasted from fourteen days to eight weeks. Cold baths reduced the temperature. Quinine was of no value, while salicylate of soda seemed to have a favorable action. For the pains, tincture of gelsemium, application of ice bags, and subcutaneous injections of morphia were valuable, while bromide of potash and warm baths were useless.

Experiments with Cotoin.

An Italian physiologist, Dr. P. Albertoni, has been studying the action of cotoin. The extract obtained by æther from the coto bark is but slightly soluble in water, but readily so in alcohol and alkalies. In small doses to persons in health, it increases the appetite and does not produce constipation. Its action in checking diarrhœas is explained by Dr. A., though its observed effects of actively enlarging the small vessels of the intestines, and thus increasing their nutritive force, which, in diarrhœa, is impaired, and the food-material remains in the bowel as an irritant. He combines the cotoin with subnitrate of bismuth.

The Vomiting of Pregnancy.

From the *College and Clinical Record* we learn that Prof. Parvin believes that very many cases of the vomiting of pregnancy are due to coitus. In the treatment of this affection, he places at the head of the list tr. nuc. vomicæ, gtt. ij-ij every two or three hours, or else gtt. x before meals. Getting the idea from the similar successful treatment of ether nausea, he suggests water as hot as it can be drunk.

Iron Subcutaneously.

Some observations on the hypodermic use of iron have lately been published by Dr. Glaeveke. He used a ten per cent. solution of the *ferrum citricum oxydatum*, Germ. Pharm., which never pro-

duced ulceration. The iron passes off by the kidneys within twenty-five hours. The place of election for the injections is the nates or muscular tracts of the back. The iron solution should be made anew every two or three weeks. Given in excess, the drug produces symptoms of general malaise, sick stomach, and prostration. Its therapeutic effects in proper cases are prompt and satisfactory.

Tincture of Iodine in Papular Eczema.

Dr. L. D. Waterman writes to the *N. Y. Med. Jour.*, that in a recent case, started by two doses of morphine acting on an idiosyncrasy, where all soothing ointments, lotions, and internal treatment failed, I painted the aggregations of papules with Churchill's tincture of iodine, putting on three coats, well dried in, each time. Two would probably have done, for it blistered the whole surface. But in five days the cuticle peeled, the skin was left sound, and all the outlying untouched eruption had entirely disappeared. The cure was complete.

The Warm Foot-Bath.

If the observations of Dr. Sciolkowsky (*Memorabilien*, No. 7, 1883), are to be credited, our usual notions about the action of a warm foot-bath on cerebral hyperæmia are erroneous. He used water at a temperature of 92° to 97°, and found that while the temperature in the rectum fell, that in the axilla and external auditory meatus was increased.

Curative Gymnastics.

In one of our English exchanges Dr. Wahltsch points out the value of modern gymnastics and massage, if executed by competent and skillful manipulators, in predisposition to phthisis, in sluggishness of the abdominal muscles and digestive organs, in strumous disease, in rickets, in spinal curvature, in uterine affections, in hysteria, and in paralysis.

An Unsuspected Source of Disease.

Since parasites do infest everything organic, we are not surprised to read in the *Rev. Scientifique*, January 5, 1884, that M. Joannes Chatin has found a parasite in the common onion that gives rise to disease. M. Pasteur, who has examined it, finds it similar to the parasite of mildew in wheat, but with less vitality. The affected plants should be pulled up and burned.

CORRESPONDENCE.

The Practice of Vivisection.

EDS. MED. AND SURG. REPORTER:—

In the REPORTER of the 16th inst., under the title, "Anti-vivisection," remarks upon this subject are made having personal application to myself, although my name is not given. Of the meeting to which allusion is made, notice was contained in most of the papers the next day, my name, with many others, appearing. My position in reference to vivisection, my opinions and acts in relation thereto, may briefly be stated. A few years ago a paper appeared in *Scribner* entitled "Vivisection, Does it Pay?" The writer (his name escapes me), treated the subject frankly, rationally, and with due courtesy, arriving at the conclusion that it did not pay, as the benefits were not commensurate with the torments inflicted upon thousands of defenceless, helpless animals. To this ensued, in the same magazine, a rejoinder from the pen of Prof. H. C. Wood, written in the earnest, frank, and decorous style of the other paper.

Some time subsequent to the issue of his paper, I informed Dr. Wood that a third paper would probably appear, advocating neither entire prohibition of vivisection, nor leaving the door open to its indiscriminate practice by every one, but simply a restrictive act. To this he replied that he could see no objection, if not too rigidly restrictive. But again, another gentleman, holding a most distinguished position in the profession, pre-eminent in his devotion to the study and treatment of obscure affections of the nervous system, and, like Prof. Wood, enjoying a world-wide celebrity by his contributions in elucidation of difficult problems in physiology, pathology, and therapeutics, has intimated to me his concurrence in the sentiment of Dr. Wood in regard to a moderately restrictive act. Is there anything surprising in this accord of opinion? There are, probably, in this country not two other persons engaged in this line of research, who so perfectly comprehend, in all points, its difficulties. These admissions, then, do honor to both head and heart, and justly merit commendation and approbation.

My own paper, entitled "Thoughts upon Vivisection, with Reference to its Restriction by Legislative Action," was read before the College of Physicians June 1, 1881, and was decidedly conservative. In view of this statement I cannot feel that there is ground for the intimation of fanaticism on my part, nor that anything said by me, at the meeting alluded to, should have excited surprise. So far as obedience to legal enactments is concerned, there will always be found those who will disregard them, yet the experience upon this point, in England, is favorable, and would probably be no less so in this country.

GEORGE HAMILTON, M. D.

Philadelphia, February 18, 1884.

Scarlet Fever Contagion Conveyed by Letter.

EDS. MED. AND SURG. REPORTER:—

Believing what I have to write will be of interest, I ask to report some cases of scarlet fever as

occurring in my practice during March 1882, which I think will be almost conclusive as to the conveyance of the contagious material long distances.

I was called March 13 to the family of Mr. Muhler to see one of his children. This child was 6 years old, had high fever; sore throat, which on inspection showed the characteristic redness of scarlet fever; had vomited some hours before I saw it; the pulse was frequent, and the nervous system was considerably affected, characterized by startings and restlessness; in fact, all the symptoms pointed to scarlet fever. I informed the parents what I thought was the trouble, when the mother said: "Doctor, how is that? I have always understood that people did not take the scarlet fever without catching it from some one else." I told her that was recognized in medicine as a fact. She said, "Well, then, this is not scarlet fever, as my children have not been off the place (this was in the country, and the nearest neighbors were a half-mile distant,) for two months." I said, "Well, I can't help that, this child has had some chance to get the disease."

This case was a typical ordinary case of scarlet fever, going through the usual changes until recovery took place. In four and five days respectively two other children came down with the disease. There were four children in the family, aged 9, 6, and 3½ years, and 3 months respectively. There was nothing peculiar in any of the cases; all recovered without accident or sequelæ.

I was curious to know how the children got the disease. The mother (who, by the way, is a very intelligent woman) informed me that the family had occupied the house for three years; said the children had not been away from the farm for two months, and that no one had been in the house who had had the fever or been where it was. In fact, I myself had not known of nor heard of a case of the disease for some months anywhere in the county. So in talking of the strangeness of the cases, and of the disease in general, the mother said they were having it in Illinois, that they received a letter from her brother only a short time before, stating that her brother's family had just lost a child with scarlet fever. This letter contained a photograph. The letter was received only seven days before the first child was taken sick, and the children all handled the letter and picture. I am convinced that the letter carried the contagious material in these cases, at least in the first case. I neglected to say that the babe three months old escaped.

E. F. COWGER, M. D.

Riverton, Iowa.

"The Question of Women Doctors."

EDS. MED. AND SURG. REPORTER:—

I notice the comment of one of your readers upon the "question of women doctors," who apparently is opposed to women entering our profession on the ground that one female is interfering with his practice. I think the doctor rather selfish, and disposed to narrow the question down to whether or not he can successfully compete with the enterprising wife of an employee of the railroad, who, being free from "responsibility," has

captured some of his best families "by talking to the ladies." Now if the doctor has been practicing in his village for a longer time than this lady, and she can take from him the "lion's share of the practice," perhaps a more enterprising male physician could have done the same thing.

The doctor says "it is not right that we should encourage those who support no one, thus to rob us of our livings." Perhaps this lady does not support a large family. Is that any reason why we should discourage lady practitioners of medicine? Is this all the doctor is practicing for, to support his family? If so, and there are many such in the profession, the sooner we have a radical change of some kind the better for us.

The doctor should remember how much greater a task it was for this lady to attain a medical education than for him, exposed to the jeers of the opposite sex in dissecting-room and amphitheatre; her *frailer* body and her physical inability to endure the hardships of the physician's life, and the avenues for acquiring a "living" that are closed to her on account of her sex.

The doctor may lose his place for a time in the best families of his village, but when some affliction of an extraordinary character appears among the children of the families he has lost, I am afraid this enterprising lady may be requested to call in the doctor who has been "doing their practice?" Why? Because she is a woman. Women have little confidence in women as physicians. When a disease of a serious nature presents itself, men, heads of families, less. And if there is a niche in medical practice that woman can fill even temporarily, don't discourage her.

If there are women who, from a modesty inborn, suffer in silence rather than consult a medical man, the sooner we have competent women for them to consult, the better for humanity.

"But in our profession," you say, "the fact is well known that it is not an easy matter for an unmarried man to secure family practice." If this is so, and we have doctors who are too poor to support a non-professional wife, let them marry these independent female M.D.'s as soon as they have completed their education; this will do away with the Dr.'s plea of lack of "responsibility," and our now unmarried physicians will be "doubly light and girded for the race." * *

JAMES M. DONELAN, M. D.

Glenwood, Iowa.

Use of Carbolic Acid Hypodermically in Hemorrhoids.

EDS. MED. AND SURG. REPORTER:—

I am induced to reply to the enquiry of Dr. S. W. D., of Virginia, in No. 7, by the request of a prominent gentleman in the profession in Philadelphia. I would respectfully refer to a report made in the July number of the MEDICAL AND SURGICAL REPORTER, 1878, page 21. The patient reported is at this time attending the Law School in Philadelphia, and has had no return of hemorrhoids. Since the date of the report I have had frequent occasion to test the power of carbolic acid hypodermically, and with unvaried success.

How to proceed: If the pile is external, you place your patient on a table with the body on the right or left side, the anal extremity to a good

strong light, the knees drawn towards the stomach; the patient assured that there will be but little pain or suffering; the operator seated. Now pack the protruding pile with cotton wool saturated with cosmoline. Charge a good new hypodermic syringe with 6 to 8 drops of No. 1 Calvert's carbolic acid (fluid), fix the needle, insert it into the protruding pile, fill the pile carefully (skillfully), and the ordinary patient can get up, go about his business, and have little or no trouble. Treat one pile at a time; if more than one, let the parts operated on heal up before another is attacked.

The pain is likened to the sting of a bee, and is followed in a moment or two with a feeling of comfort. The pile being in a state of inflammation does not forbid the treatment, but rather invites it.

The periods between treatments may be 6 or 8 days. I allude to cases where more than one hemorrhoidal tumor presents itself.

When the enlargements or hemorrhoidal tumors are within the anal opening or contraction, a rectal speculum may be used, and can be gotten at any good instrument-maker's—I prefer those *with a slide of glass*. Place the sufferer on a table as before directed, take a small gutta-percha vaginal syringe, charge it with sweet oil, enter the anal region with it and anoint the rectum, withdraw the syringe, and introduce the rectal speculum. The natural color of the mucous membrane lining the rectum is "pale pink—almost white," an internal pile "sack" is of dark red or purple color, showing congestion.

The speculum should be so placed as to show the purple engorged spot; the glass slide should be carefully and slowly withdrawn until the engorged mucous membrane drops in a situation to be reached with the needle of the hypodermic syringe. The needle for internal operations should be about three inches long, and have a partially bent point—the bend to be just at the point. Piles are usually in the verge of the anus, or on either side of the internal region. I have never found them back or front.

Several times there has been some hæmorrhage, which has always yielded to the application of a solution of ferri subsulphas, either locally or by injections.

J. W. C. O'NEAL, M.D.

Gettysburg, Pa.

NEWS AND MISCELLANY.

The Effects of Cotton Sizing on the Health of the Operatives.

The *Med. Times and Gaz.*, December 8, 1883, contains the following practically valuable remarks:

Dr. J. H. Bridges and Mr. E. Haydon Osborn, the Commissioners appointed by the Home Office to inquire into the effects upon the operatives of the process of heavy sizing in cotton manufacture, state in their report that though notable changes have taken place during the last ten years in the proportion of the various ingredients used in the process, the amount of dust in weaving-sheds has not proportionately increased. There is no doubt that the change effected by steaming the atmosphere of weaving-sheds is to create an artificial

climate of a somewhat tropical and relaxing kind, whilst there is a great unwillingness to admit fresh air into the weaving-sheds owing to the artificial and unstable composition of the warps. During frosty winter afternoons, and when steam-jets have been for hours in full operation, and when the products of gas combustion have been added to the exhalations from the lungs of the work-people, the atmosphere of a weaving-shed must be in a high degree injurious to constitutions predisposed to pulmonary disease or dyspepsia. The conditions of the work are not such as to prevent that large proportion of work-people whose constitutions are naturally vigorous from following their calling without serious inconvenience. But there remains the proportion, always very considerable, who have a constitutional tendency to one form or other of rheumatic, phthisical, or dyspeptic ailments. Such tendencies cannot fail to be intensified by working continuously in an ill-ventilated atmosphere pervaded by mineral dust or rendered artificially damp. The remedies recommended by the Commissioners are—first, that those processes by which very large quantities of size can be incorporated with the warp without necessitating the diffusion of dust or moisture, but which are at present trade secrets, should become generally known and applied. Secondly, that more effective means should be taken to apply these means where they exist. In many dusty occupations, notably in that of flax-heckling, it is a most important mitigation of the evil that they are carried on with open windows. The air of the work-room, where this is the case, is probably changed more than a score of times during an hour. It may be doubted whether with the majority of weaving-sheds it is effectively changed once during the working-day. Thirdly, that as the business of weaving has become from various causes one of great complexity, and requires an amount of skill, and even of scientific knowledge, such as appeared to the Commissioners to be not unfrequently wanting, measures should be taken for diffusing elementary information with regard to the qualities of the atmosphere. In a manufacturing process in which the quality of the atmosphere is so important, it might have been expected that means would be taken to ascertain with some precision facts capable of such easy and exact measurement as temperature and moisture. Yet it is very rare to find a thermometer in a weaving-shed; and a hygrometer, simple though the instrument is, appears to be entirely unknown. The diffusion of elementary information on these two points, combined with a recognition of the paramount importance of ventilation, would go far towards the provision of remedies, or at least of effective palliatives, for the evils complained of.

Contra-indications for the Administration of Anæsthetics.

After reporting a case of death from heart-clot following etherization (*Boston M. and S. Jour.*, December 13, 1883), Dr. Francis Minot says:

So far as we are justified in drawing conclusions from a single observation, we may learn from the above case:

1. That etherization is not altogether safe for a

patient with a large effusion in the chest, and should not be employed if it can be avoided.

2. That when employed, unusual care should be taken to prevent accidents, and especially that the patient should be inclined towards the same side with the effusion.

The case also confirms Dr. Bowditch's law, that the presence of blood in the fluid removed from the chest is a strong presumption in favor of cancer of the lung or pleura, or both.

The Berlin Polyclinic.

This institution celebrated last November its first anniversary day. During this time more than two hundred medical men, amongst them many strangers, have visited the Berlin Polyclinic, in which at present the following specialties of medicine are taught:

1, Ophthalmology; 2, Operative Surgery of the Eye, and Practical Instruction in the use of the Speculum Oculi; 3, Neuropathology and Electrotherapeutics; 4, Laryngoscopy and Oesophagoscopy; 5, Otolary; 6, Physiology; 7, Dermatology; 8, Syphilology; 9, Histology; 10, Forensic Chemistry.

These specialties are taught in monthly courses, which begin every first working day of the month, and last every day during the whole month, except Sunday and holidays.

To the Berlin Polyclinic two laboratories, one for chemistry and one for histology, are attached. In both, medical men find ample opportunity for executing researches on scientific objects. The first of January a third laboratory, destined for working in bacterioscopy, will be opened. At the same time a monthly course of bacterioscopy will be united to the other courses.

A Good Example for County Societies.

In view of the enormous number of half-cut doctors that are annually licensed to prey upon the community, it affords us pleasure to note that the Trumbull County Medical Society, of Ohio, at its meeting January 31st, passed a series of resolutions which provides for securing a preliminary examination of all proposed students of medicine who enter the offices of the members of the society.

A board of examiners is appointed, before which all applicants for admission as students of medicine under the tuition of members of the society must pass a satisfactory examination in fourteen different subjects. The examination is in fine about the equivalent of that demanded for admission to a classical college.

Medicine among the Primitive Irish.

In the *Dublin Jour. Med. Sci.*, January 1884, Dr. A. Macalister tells us that the primitive Irish did not, apparently, consider medical science as a branch of general culture; and from O'Flaherty we learn that in the University founded at Tara in the third century by Cormac MacArt, the schools were of military science, of history, and of law—none of medicine. In these, and even later in early Christian times, the physicians were a set of hereditary dependents attached to the leading septs or families. Thus the O'Hickeys were the physicians to the O'Briens of Thomond; the O'Lees to the O'Flahertys; the O'Shoils to the MacCoghlan and to the MacMahons of Oriel.

A Portable Disinfecting Oven.

Dr. Albinois, of Marseilles has designed a portable disinfecting oven which, it seems, possesses much merit. It can be carried from place to place, since four men can easily handle it. Half an hour and a very small quantity of fuel suffice to produce the necessary heat, and there is a small vessel for the evaporation of fumes derived either from thymic or carbolic acid placed within the oven. The apparatus is made of iron, and only costs \$110.

The Moses Taylor Hospital at Scranton.

Mr. Moses Taylor, of New York, bequeathed \$250,000 to this hospital; and now his daughter and her husband, Mr. and Mrs. Percy Pyne, have presented \$100,000. It is a great pleasure to record charitable bequests to hospitals and educational institutions, and we only wish that we had much more of it to do.

Where American Pork Can Go.

The Department of State has received a telegram from Mr. Eugene Schuyler, United States Minister to Greece, saying that the prohibition of the importation of pork from this country into Greece has been abolished.

Items.

—Prof. Bartholow strongly recommends salicylic acid, either by injection or internally, in large doses, for cystitis. Administered by the mouth, it acts after being excreted in the urine.

—Panklastit, a new explosive, said to be more powerful than dynamite, is made by the action of hyponitric acid—generated by heat from nitrate of lead—on carbon bisulphide.

—An interesting pathological and clinical account of cases of trichinosis observed during the recent severe epidemic at Emersleben may be read in the *Gazette Médicale de Paris* for January 12.

—The immense crematory at Rome is in almost daily use. Cremation is becoming daily more popular, and bids fair soon to dispose of more corpses in the Italian capital than does the old-fashioned burial.

—Prof. Gross suggests the following:

R.	Tinct. cantharidis,	3 iss.
	capsici,	gtt. xx.
	Glycerini,	3 ss.
	Aque colognensis,	q.s.ad 3 vj.
Sig.	—"Hair Tonic."	
		M.

—Prof. Gross strongly cautions against telling a man with a history of any kind of a sore on his penis that he does not have syphilis, until three months have elapsed from the last connection. The sore may not be a chancre, but a chancre may be incubating.

—Nature reports that Prof. Heiberg, of Christiania, has demonstrated the presence in the air-passages and pulmonary substance of hares of a form of strongylus, both barren and charged with ova, which would appear to be the cause of an otherwise unexplained mortality among these animals in the autumn of last year in the district of Eidswold, in Norway.

—A set of rules regulating the mode in which medical instruction is to be imparted to women in local colleges, and setting forth the terms upon which females are to be admitted to medical degrees, has been published under the authority of the Bombay Government.

—At the meeting of the Royal and Imperial Society of Physicians at Vienna on October 19 (*Wien. Med. Blätter*, October 25), Professor Drasche gave some information regarding the spread of cholera by means of washing; three laundresses in a laundry in Dornbach having fallen victims after washing clothes from hospitals in Vienna, where sporadic cases of cholera had occurred.

OBITUARY NOTICES.

JOHN L. H. SESSUMS, M. D.

Dr. John L. H. Sessums died at Lonoke, Ark., after a lingering illness, January 19, 1884. He was a graduate of Bellevue Medical College; a good physician, a fine surgeon, an honorable citizen.

DR. GEORGE P. OLIVER.

Dr. George P. Oliver, President of the Medico-Chirurgical College, died suddenly on Wednesday night at a meeting of the Knights of the Golden Eagle, of which he was the founder. Dr. Oliver, who was about 56 years of age, was born in Kensington, Philadelphia, and all his life, with the exception of a few years spent in New York, has resided in this city. He was a graduate of the Philadelphia Medical College in 1851, and of the University of Pennsylvania in 1859. He was a prominent member of a great many Orders, among which were the Masons, etc.

DR. J. R. EVANS.

Dr. J. R. Evans, who died recently of paralysis at his residence in Branchtown, Pa., was one of the most prominent physicians of Bucks county. He was a member of many medical societies and the Masonic fraternity. He was 57 years of age, and a very large and muscular man, weighing 250 pounds.

DR. CHARLES M. FORD.

Dr. Charles M. Ford, a prominent physician of Washington, died lately at his residence on Capitol Hill. Dr. Ford was about 43 years of age, and was a native of New York. He studied his profession in Philadelphia, and after being graduated, entered the Union Army as a surgeon attached to a New York regiment.

QUERIES AND REPLIES.

EDS. MED. AND SURG. REP.—

Has the amputation of the uvula in males or females anything to do with sterility?

By placing this among your "Queries and Replies" you will greatly oblige
B.

Dr. B. B. G.—Your inquiry is answered by the letters of Drs. O. Neal and Barr on the carbolic acid treatment of piles.

Dr. Alphonso, of Pa.—As an excellent prescription in dyspepsia we give:

R.	Jensen's pepsin,	grs. 192
	Sherry wine,	5viss.
	Glycerin puris,	3iss.
	Acid tartaric,	gr. v.
M.	S.—f. 5j. after meals.	(Gr. iij. to f. 3j.)

Dr. J. G. S., of California, writes to inquire of readers the best treatment for the following case:

"Six months ago I attended a patient in her 'first labor.' She made a good recovery. For the past four months she has had no control over her 'bladder.' 'Incontinence' of urine whenever she stoops over or coughs. The 'walls of the vagina' seem to be completely collapsed and fill up the passage; the 'womb' but slightly prolapsed."

Ans.—Excision of the vaginal walls with a view to promote narrowing by cicatrization would seem to offer a fair hope in such a case.

EDS. MED. AND SURG. REP.—

In reply to Dr. S. W. D., of Virginia, concerning use of carbolic acid, hypodermically, in hemorrhoids.—During the last four years I have used this treatment; also advised and assisted in its use beside my own cases. Result always favorable and permanent, the indication for treatment being an indurated internal ulcer. Frequently, when several are present, the treatment of the largest will relieve the entire trouble. Very little pain follows the application. Let the bowels be moved by light purgatives in morning, and cleansed by injection just before operation. Inject into centre of largest ulcer two or three drops pure carbolic acid; follow with opium suppository, and rest in bed a few days. This treatment has afforded me much more satisfactory results than any other. Respectfully,

D. M. BARR, M. D.

1902 Spring Garden street, Philadelphia, Feb. 18, 1884.

MARRIAGES.

BRACKEN—ROBINSON.—At Rockaway, N. J., February 13, 1884, by the Rev. Albert Erdman, D. D., Henry Martyn Bracken, M. D., L. R. C. S., Edinburgh, of Thompson, Conn., and Emily M. L. Robinson, of Morristown, New Jersey.

DIEHL—LIVINGSTON.—At Hoboken, N. J., Thursday, February 14, 1884, by the Rev. George C. Houghton, Dr. William Diehl, of Philadelphia, to Annie, daughter of I. Menzies Livingston.

GRAY—BARNETT.—At the residence of the bride's parents, in Louisville, January 27, 1884, Dr. D. A. Gray, of Little Rock, Ark., and Miss Isora E. Barnett.

HENSCHEL—KNOEDLER.—At the residence of the bride's mother, in New York, on Tuesday, February 5, 1884, by the Rev. Father Ducey, Edward K. Henschel, M. D., and Marie Leonie, daughter of the late M. Knoedler.

KING—CLIFTON.—At the residence of the bride's parents, 1427 North 12th St., this city, on Wednesday evening, February 13, 1884, by the Rev. Jos. D. Newlin, Dr. William R. King, of Washington, D. C., and Miss Helen P. Clifton.

MATHERS—MILLER.—At the residence of the bride's sister, Park avenue, Walnut Hills, Cincinnati, Ohio, February 14, 1884, by the Rev. Jas. Stanley, T. H. Mathers, M. D., of New Westminster, British Columbia, and Ida May, second daughter of Wm. Miller, Esq., Cincinnati.

SHIPLEY—TABOR.—At the home of the bride, February 3, 1884, Dr. Henry T. Shipley, of Lisbon, Dakota, and Miss Mary Jennett Tabor, of Frederickstown, O.

STEANS—FOSTER.—In Millinburg, Pa., February 5, 1884, by Rev. W. I. Steans, assisted by the Rev. Isaac Grier, D. D., John Charlton Steans, M. D., and Elsie Chambers Foster.

DEATHS.

BRODHEAD.—At his hotel in Waynesboro, Burke county, Georgia, February 6, 1884, Dr. Cicero Brodhead, of Delaware Water Gap, Pa.

EVANS.—In this city, February 9, 1884, Dr. J. R. Evans, aged fifty-seven years.

KENDRICK.—In New York, after a short illness, Dr. Thomas C. Kendrick, in the fifty-sixth year of his age.

WATTLES.—In this city, February 12, 1884, George H. Wattles, M. D., aged thirty years.

LECTURE.

CLINICAL LECTURE ON DELIRIUM TREMENS.

Translation from Dr. Benjamin Ball's work on "Mental Disease" (Paris, France), by Dr. Adele Gleason.

There is a pathological state situated, as it were, on the frontier of acute alcoholism and chronic alcoholism, and which resembles a bridge passing between the two great phases of alcoholic intoxication. It is delirium tremens, or trembling delirium—a grave affection, and one which seems to bear the same relation to ordinary alcoholism, that of aggravation, which acute delirium bears to the maniacal state.

Gentlemen, from the earliest times in medical history, drunkards have been cared for, and cases of delirium tremens have been observed. Hippocrates has certainly reported examples; Aristotle seems to have described the symptoms in Denis, of Syracuse, who had a bout of drinking lasting twenty-four days (a truly royal orgie). In fact, our predecessors of the last two centuries have left us observations which evidently relate to it. And nevertheless, the name is of recent date, and it is scarcely sixty years since the existence of an acute disease, offering a special pathology, has been recognized, and its origin established in alcoholic impregnation.

It was in 1813; the wars of Napoleon were in full activity, and contraband goods coming to the shores of England and to the nearer of the continental shores, and especially in the county of Kent were there enormous quantities of foreign alcohols. The maritime population of these par-

ishes abused, consequently, the use of all the strong liquors, that they contributed to introduce into the country. Then it was that Sutton, who practiced medicine in those parishes, was struck by seeing that there existed among these people, and especially with the sailors, a sort of fever, accompanied by trembling, which was cured by opium, but aggravated by bleeding. To this special form of mania, he gave the name of *delirium tremens*, without attaching directly to these attacks the abuse of alcoholic liquors as a cause, as it is only aside from the work of Sutton that delirium tremens has been recognized as a thing by itself, as a special disease.

Six years later, Rayer published a memoir in which he traced those attacks to their real cause, and made the word *oinomania*, which has not survived.

We come, then, to the works of Blake, Ware, Copeland, Calmiel, and several other authors, who make known the nature and symptoms of this affection.

In 1826, Dupuytren pointed out the nervous delirium of the wounded and those operated upon, which he regarded as a special state. We know to-day that these are simply cases of delirium with trembling, developed by an accident or wound in subjects addicted to the abuse of alcoholic liquors.

Finally, Gubler, and more recently MM. Motet and Magnan, have studied this question with great care, and it is to be found reviewed in the great medical encyclopedias published in France and Germany.

In our day it is invariably admitted that delir-

ium tremens is produced a *potu nimio*, or rather a *potu suspensio*.

But we may ask ourselves whether the alcohol is always of necessity the point of departure. Opium and prolonged intellectual exertion, have been accused, especially in young girls. Such, at least, is the result of the observations of Johnsen. But we should be very cautious in such cases, above all in the case of young Englishwomen; for alcoholism, little known with us among the women of the upper classes, is often met with in the best English society, the members of which have often in their bureau drawers a secret consolation, to which they have recourse in all the afflictions of life.

Let us cite on this point an observation of Rayer to how great a degree we must distrust appearances: A cook had been all day employed in cleaning out a bureau in which several bottles of cognac and kirsch had been overturned. Following this work she was taken with an attack of delirium tremens, which was attributed to the vapor of alcohol, for the sobriety of this woman was vouched for. But a week later she had a second attack, and this time they thought she must be dismissed. Some days later she was found dead drunk in the street. It is then perfectly allowable in practice to distrust appearances.

Following this rule, one is rarely deceived, if using the greatest care in observation. We will leave aside from this lecture all the cases, more or less authentic, which are not related to alcoholism, and we will occupy ourselves exclusively with those which recognize as their origin the intervention of this toxic agent. But at the threshold of the question, one of the most important distinctions becomes obligatory, and dominates the entire history of the disease.

The habitual use of fermented liquors causes a special predisposition, and in subjects this predisposed delirium may break out, either on the occasion of an unexpected accident, or from the suppression of the usual excitant. Hence, we must include among the causes of delirium tremens all those acute affections which may happen to alcoholics, more especially wounds, pneumonia, pleurisy, acute articular rheumatism, typhoid fever, scarlatina, and erysipelas, especially of the scalp. We must add to these the greater part of the causes of enfeeblement, such as inanition, suppuration, and even blenorrhagia, intellectual work, prolonged watching, venereal excesses, and keen moral emotions. Bennett, quoted by Tweedie, reports the case of a young man who, discarded by his father on account of bad conduct, was

seized almost immediately by an attack of delirium tremens.

Such is incontestably one of the etiological forms of the disease: the gun is loaded, it is fired, but not by itself—there must be a shock to determine a discharge.

There is another etiological form in which alcohol itself is not sufficient. It is met with in all those men who are habitual tipplers, but so with discretion and without great cause for scandal; it is also met with among workmen who labor in courts where the atmosphere is charged with alcoholic vapors. In short, delirium may break out abruptly as a consequence of an orgie.

We must add, after the causes, certain general predispositions.

Let us cite age first. With men it is mostly from thirty to fifty years of age that the disorder breaks out. With women it is generally at the time of the menopause, the time in which alcoholic tastes usually develop.

The influence of the season is also to be noted. The heats of summer appear to be specially favorable. The enfeeblement of the general health appears to create an equally baneful predisposition in this respect.

But one of the principal factors is incontestably heredity. The descendants of alcoholics are always specially inclined to commit excesses, the consequences of which are not well born. There exists on this head a very marked difference in human races. Thus it is that in the extremes of Africa, the Hottentots, drunkards *par excellence*, are rapidly enfeebled by the use of alcohol. The Caffres and the Zulus resist much better. They also become intoxicated when they have occasion; but they are of a superior race, full of energy and intelligence and military qualities. We hence understand how they resist the effects of a poison which triumphs easily over inferior organizations.

There remains finally the influence of the suppression of the stimulation. Pointed out by Cumming and Blake, it has been controverted by Laycock and Anstie, but it is to-day universally admitted.

These etiological points once established, let us look at the evolution of the disease. These attacks are almost always announced by prodromi.

Delirium tremens has doubtless been seen to break out even in the course of a prolonged orgie, but it is well known that the first manifestation of the disease is precisely dipsomania, the desire for intoxication.

Thus it often happens that the debauch is an

effect, and not a cause. Cumming reports the saying of a young girl, who said of her father: "We always have warning when an attack is coming on, for he begins to drink and becomes ugly."

Among the prodromi of the attack some are physical and some psychological. Among the former, we cite, first, gastric troubles, pericardial distress, cephalalgia, vertigo, excessive perspiration, slight tremulousness of the hands and tongue, accompanied, sometimes, by a certain embarrassment in speech; and sensorial disorders, such as hyperæsthesia, and even hallucinations of sight. Finally, sleep is troubled, and if the patient escapes insomnia, he has nightmares and terrifying dreams.

The instability of character and nervous uneasiness are the principal psychical troubles that are observed at this period. There is often a profound moral depression, associated with a vague terror, of which the patient can not give the cause.

This painful state may last from a week to a fortnight; but at last delirium breaks out, and as the first and principal symptom, it presents absolute insomnia.

The physiognomy of the patient, much disturbed, indicates clearly enough the disorder of the mind; the laggard eyes, the wrinkled features, the expression of terror upon the whole face: he comes and goes, is agitated, and gives contradictory orders.

A psycho-sensorial phenomenon of the highest importance is added to these diverse troubles: there are hallucinations. They relate more especially to sight; the patient perceives climbing figures, fantastic objects, and above all, animals of all kinds and all grades. Sometimes, also, but less often, he experiences hallucinations of hearing and of touch. A patient, recently in the clinic, saw himself pursued, in his delirium, by flies, who stung him cruelly.

Hallucinations of sight, with alcoholics, predominate in obscurity; they are more marked at night than in the daytime, and even during convalescence, at the time when they seem to fade away, they reappear often when the patient closes his eyes.

Another characteristic of hallucinations in the alcoholic, is that they are almost always aggressive. The personages which surround them seem to menace them; dogs show their teeth, rats would bite them, flies sting them; and these intellectual phenomena are marvelously well united with creeping sensations, with burning and pains which they feel in the skin.

Another accident very frequent with all the insane, is well shown in this form of delirium; it is the fear of being poisoned, from whence often comes the obstinate sitophobia that is presented by some of these patients.

(To be Continued.)

COMMUNICATIONS.

BLOOD-LETTING IN THE OLD.

BY HIRAM CORSON, M. D.,
Of Conshohocken, Pa.

(Continued from page 262.)

On the 8th of June, E. S., aged 77, consulted me on the propriety of his being bled. The doctor in his neighborhood would not bleed any one. He complained that he could not sleep well; had an unpleasant feeling in his chest, was very costive, had flying pains through his body, and could not make much exertion for more than a few minutes at a time. His heart was beating irregularly—a few regular beats, then a pause, then several quick, rapid beats, or perhaps a renewal of the usual beats, with a pretty strong impulse against the ribs, but with no valvular difficulty. Some persons who are favorable to bleeding healthy people, are greatly afraid to bleed those whose heart now and then loses a beat, or has now and then fluttering, as they call it; but as I have often seen such persons bear the loss of blood very well, I did not hesitate here, as he had already tried purging and other home remedies. I bled him pretty freely, and he expressed himself as feeling easier in the chest. I stayed twenty minutes or more, and when I left he walked out with me to the carriage, and said he thought he felt better. He has since been much better than before his loss of blood. This irregularity of the pulse is regarded by many physicians as a condition which forbids the loss of blood, though there be serious disease elsewhere which might be relieved by bleeding or cups. I may therefore say here that I have frequently bled persons whom I knew to have that condition of the heart, without any injury. And two years ago my young friend Dr. Oscar Leedom bled me, then in my seventy-sixth year, moderately, for the relief of a pain over my right eye, which had been increasing for two days. It gave me entire relief in a short time.

The irregular action referred to above—losing a beat, sometimes five or six of them, in a minute, and sometimes not one for hours, or perhaps days

—has been going on with me for many years; and yet I did not fear to be bled, and it relieved me, after bromide of potassium and nervines had failed, and digitalis could promise no relief for many hours, if at all. Why, then, should I have dallied with them, when there was at hand a speedy, safe, efficient remedy?

January 2, 1876, while in attendance at the house of John Rex in Philadelphia county, his mother-in-law told me that she had had for a couple of days a dull, heavy feeling in the forepart of her head, and wished to know if I did not think bleeding would relieve her; that she had been bled frequently, but not during the last several years. I suggested that she take a mild cathartic, and if she should not be better when I should make my next visit, I would bleed her. On the 4th I was there again, and as she had had no relief concluded to bleed her. On pushing up the sleeve of her dress, I found an arm so thin and wasted as surprised me; and on looking at the back of the hands, the skin was so thin and silky-looking, with brown spots and blotches here and there, that I knew at once she must be quite old. Every tendon and vein could be seen almost as plainly as if there had been no skin over them. Every physician of long practice has seen such hands, but never save in very old people. For a moment I was doubtful if I should go on, and on asking her age, she said: "If I live till September I will be ninety-one (91)." This was a surprise to me. She saw it, and immediately said, "I am not too old, am I, to be bled?" "No, it will relieve your head." I thus reasoned the case with myself: Here is a woman who is generally well, but very old, takes but little exercise, and now has symptoms which, in persons of even fewer years, have in thousands of cases heralded the coming of paralysis or apoplexy. What the precise condition of the brain is I do not know; but it may be a local congestion which may be relieved by taking from her arm, while in a sitting position, a few ounces of blood. A few ounces may do, in this old woman what could only be effected in a strong, healthy one by from a pint to a quart. I have so often removed such symptoms, and averted, as I believe, attacks of palsy by a timely bleeding, that I think it much safer to bleed her than to omit it. She was bled nine ounces, without feeling faint. Two days later I was there again, and on asking her how she felt, she said: "I am perfectly well now. I felt it do me good before you left the house." She continued well until last fall, when she died after a brief illness, in her ninety-sixth year. This case will be regarded as

evidence of my recklessness. Let us now suppose that all these cases would have done well without any medication, or, even go further; under treatment by the opponents of blood-letting—those teachers who tell the students that patients have no blood to spare—what then do they prove? That it is a most harmless measure; that people can "spare" a few ounces of blood without danger; and that young men who graduate in medicine without knowing this are unfit to practice medicine, and that their teachers have failed to perform their whole duty.

I may here say that all the persons spoken of here as having been bled from two to six years or more ago are now living, save the one who died in her 96th year. Mrs. Cline is in her 91st year; another in his 78th; myself in my 80th; Mrs. W. in her 68th; Mrs. N. J. in her 71st, and S. G. in his 71st. I might add scores of cases of old people bled by me during a practice extending over fifty-five years, and all with relief, so far as my memory goes. If the testimony of those, even in a single county, who have long practiced, could be published, what an array of proof we would have of the value of blood-letting in saving life in cases of apoplexy, pneumonia, pleurisy, peritonitis, and in averting death in threatened attacks of paralysis in old people.

As this is an important subject, and as in the diseases which I have named and in some others where it is so efficient, the teachers in our two great medical schools are denouncing blood-letting, talking about the blood being the "organ of life" and not a drop should be lost, thus filling the students with dread, I feel that it will be proper to refer your readers to the valuable paper on this subject, written by Dr. Joseph Stubbs, of London Grove, Pa., published in the *REPORTER* of July 8, 1882. Every student of both medical colleges should read it, as should also the students of the Woman's Medical College. Should they do so, we might hope, hereafter, that pneumonia would not sweep off our eminent medical men and other valuable citizens, as it has done for the past few years, under a treatment as much to be feared as the disease itself.

Dr. Stubbs writes: "Second month, 26th, 1881, I was called to see Dr. Ezra Michener, who gave me the following history: 'I am now in my eighty-seventh year. Five days ago I fell on the ice, and sustained a fracture of the humerus near its upper extremity. There was no displacements. and it appeared to be doing well. Last evening I was quite chilly, without sensible cause, had tenderness and aching in submaxil-

lary glands, more marked on the tonsils. On retiring, the signs of the evening had passed away, and were replaced by others of a graver character. I now had pronounced fever, with weight and a burning sensation in the right thorax. The breathing was oppressed and hurried, more so when lying down. These symptoms were persistently aggravated during the night.'

"I found him with a dry, hot skin, pulse frequent and feeble, or rather oppressed, breathing short and oppressed, with pain increased by cough, or attempting to draw a full breath. My diagnosis was pneumonia, to which conclusion he arrived. I said to him: 'Doctor, notwithstanding your views in reference to blood-letting, you would not advise it here on account of your age. You are too old to be bled.' The prompt reply was: 'That must be tried. I do not know that age should make any difference. If I have but a little quantity in store, a proportionate quantity should afford relief, especially now, while in the congestive stage. If thee does not wish to use the lancet, I shall be obliged to use it myself.'

"He was bled while sitting up, and when he drew the first free breath, the blood was stopped. On recurring to the vessel, it was found to contain $\frac{3}{4}$ xv. of blood. . . . I had no case left to report. The disease was *suddenly* and completely aborted, and required no more attention."

Such is an abridged history of the case reported by Dr. Stubbs. And how instructive! A man 85 years of age, with a fracture of the arm of five days' standing, attacked by the disease which has, within a few years, swept away from us a host of our eminent men, all much younger, with an illness of only a few days, their death-beds surrounded by eminent physicians busy in diagnosing the disease, earnest in declaring it *typhoid* pneumonia, and on that account feeling justified in not resorting to that means of relief which has saved thousands from premature death. Typhoid indeed! I know no typhoid pneumonia—never recognize such a disease. What was Doctor Michener's "pulse frequent and feeble, or rather oppressed; breathing short and oppressed"?

Now suppose one of the enlightened physicians of the times had been there, and prescribed one of these "heart tonics," or some one of the now specifics to bring down the pulse, allay the heat, and thin or thicken the blood, as some great German experimenter may have suggested for such a case; what, after this, would have been his situation in a few hours? It would have been one of those cases called typhoid, which they would not expect to cure in so old a man, and

which for them would justify the use of this or that, to see how it would act. Of Dr. Michener's case, Dr. Stubbs says:

"It presents three striking features:

"1. A rapid and extensive congestion of the lung.

"2. A high grade of morbid action tending to destruction of important vital tissue.

"3. A sudden and complete arrest of the disease by blood-letting alone."

Let no one fail to read Dr. Stubbs' whole account of his case. In order to have the opinion of Dr. Michener on the subject of bleeding aged people, I wrote to him in relation to it. To-day, December 21, 1883, I received a reply from which I copy the following:

"I have repeatedly used the lancet in persons varying from 75 to 80 years, with equal advantage as in those of younger years. Some of them were cases of bastard pneumonia—*peripneumonia* botha of authors—in which I have found it to afford very prompt relief, showing that the imminent danger of suffocation is caused by congestion of blood in the pulmonary tissues, rather than by serous effusion into the air-cells of the lungs. The latter appears to be a mere sequence of the former.

"While on this subject, I will relate another form of disease in which I have used the lancet most happily under very adverse circumstances, surely, if modern teaching be true. I will give one case. John Mull, an industrious and healthy farmer, who had recently become intemperate—after several days of extreme exposure to wet, cold, and to whisky—returned home sick on the 25th of 3d month, 1829, and went to bed, where he laid without medical attendance or much nursing. On the first of the ensuing month, I was called to him. As I approached the house, his loud, stertorous breathing was quite audible in the public road. I found him profoundly comatose, the extremities cold, stiff, and pulseless; mouth and eyes set wide open; the respiration not more than five or six. I had a year before treated an analogous case, and the result led me to adopt a similar course. While hastening the preparation of more general and warm stimulating appliances, I at once placed the hand and arm in pretty warm water, with active bathing and frictions till it became more warm and supple, and then applied the lancet. A single drop of thick, pitchy, black blood followed the blade; as the frictions were continued, there was another and another at shorter intervals; each successive portion becoming more fluid and less pitchy till it

flowed, a stream of blood. When the blood had reached six ounces, there was a very obvious change in his condition, and at 12 ounces he was quite cognizant, and the bleeding was stopped. I only state the facts of the case, leaving others to draw their own conclusions. Convalescence was speedy and complete.

The other case mentioned scarcely differed save in the name. Such is the report of Dr. Michener, a man of unimpeached truth and integrity, when speaking of things

"All of which he knew,
And part of which he was."

Shall we listen to French and German teachers, of whom we have no knowledge, and shut our ears against Prof. S. D. Gross, Drs. Michener, Atlee, Green, and Benjamin Wilson, our own men, who have spoken to us words of truth and earnestness, in praise of blood-letting as a safe and efficient remedy for that disease which has been recently so fatal in our profession?

COD LIVER OIL AS A SURGICAL DRESSING,

BY J. E. HAINLINE, M. D.,
Of Cantril, Iowa.

Through the columns of your valuable journal I desire to call the attention of the profession to the use of cod liver oil as a surgical dressing.

The knowledge I am about to communicate is based upon actual practical experience, and the oil used the *purest* to be found in the shops.

In 1875 I was consulted by a lady, who told me she had a large tumor in the left mammary gland which was causing her considerable anxiety. Her friends told her it was a cancer, and that she ought to have it attended to at once. After thoroughly examining the tumor I told her it was malignant in its nature, and that the better plan would be to have it removed by the knife. This she concluded to have done. I gave her about two weeks' preparatory treatment, and then, with the aid of my two colleagues, removed the tumor, together with several axillary glands. After securing several small vessels and thoroughly sponging the wound, closed the same with several sutures (silk) and a few small strips of adhesive plaster, after which I applied the simple water dressing, allowing it to remain undisturbed for forty-eight hours. I then removed the dressings, found the wound doing nicely, and then I applied the cod liver oil dressing. This I did once a day, always cleansing the wound first with castile soap and warm soft water. On the sixth day the wound

was torn open by the patient while about half asleep. I had neglected to pinion the hands to prevent her scratching. She said "the place" had been itching terribly, and she had attempted to scratch, and in so doing had torn it. I found there was an opening about three inches long by one and a half wide. This I determined to heal by granulation, and thereby prevent deformity of the breast. The wound was quite deep. After cleansing it thoroughly, I applied the cod liver oil, to which I had previously added a few drops of carbolic acid. The wound healed rapidly, and the granulating process was perfect in every respect. The patient made a rapid recovery, and up to the present writing there has been no return of the disease. The diagnosis was "*encephaloid carcinoma*."

The dressing in this case being a new feature, I determined to examine several surgical works for the purpose of obtaining, if possible, some evidence of its previous use. I did so, and not finding a single instance, I concluded I must surely be the originator.

I addressed Prof. S. D. Gross, and laid the above case before him, at the same time asking him if he had ever used the above-named dressing, or had ever known of its being used by any surgeon.

I received a prompt reply from Dr. Gross, stating that he "had had no experience with cod liver oil as a surgical dressing," but advised me to continue my experiments, noting carefully the results, and report the same.

These experiments embrace a class of cases differing entirely from each other. In every instance the dressing seemed to increase activity, thereby promoting the healing process.

To enumerate and describe all the cases in which I have used this dressing would require too much valuable space in your journal, so I will only mention a few in connection with the one above cited.

In the spring of '76 I excised a scirrhus breast, after which I applied, first, the simple water dressing, allowing it to remain 36 hours, after which I applied the cod liver oil dressing, to which I added daily a few drops of carbolic acid.

The wound healed rapidly, and on the sixteenth day my patient returned to her home, with instructions to report to me at my office once per week, and to apply the dressing as she had seen me do. I also prescribed an alterative mixture to be taken an hour after meals.

When my patient left for her home the wound was nearly healed, and when she returned a week

later, it had entirely closed. Up to this time there has been no return of the disease, and the lady to-day is enjoying pretty good health.

Three years ago I operated upon a young man 23 years of age, for necrosis of the tibia. I removed a large portion of dead bone, and, after scraping the cavity, carefully filled it with surgeon's lint, which had been previously dipped in a solution of corrosive sublimate. This I permitted to remain for 24 hours, when I removed the same, cleansed the cavity thoroughly, and again introduced the lint, this time saturated with the cod liver oil and carbolic acid.

In this case, also, I prescribed an alterative mixture combined with tonics. In no case where I have operated, using the above-named dressing, did there occur a more perfect and rapid recovery than in this particular one.

Desiring to know the condition of my patient at this time, I wrote him and received the following reply:

"In regard to my leg, I will say it has given me no trouble for nearly two years. I have been working at my trade this winter (he is a blacksmith), and have been on my feet a great deal; but my leg has not hurt me, and seems as strong as ever it did."

Thus I might go on citing over a hundred different cases in which the cod-liver oil, with the addition of carbolic acid, was the only dressing applied; but will be content, for the present, with those above mentioned.

In every case I was compelled to note the increased vitality.

My experience with cod liver oil as a surgical dressing has led me to use it exclusively, believing it to be superior to the olive oil generally used.

To those who may desire to test the virtues of this new dressing, let me suggest that they use the *purest article to be found in the market*.

FRACTURE OF THE FEMUR IN CHILDREN.

BY D. B. HOLSBURG, M. D.,
Of Granville, Ill.

Every practitioner is aware of the difficulties attending the treatment of fractures in children, and more particularly those of the femur in its upper third. In adults almost any of the ordinary modes of dressing may give satisfactory results; but in children, who look upon the doctor as a sort of tyrant, and all modes of confinement as punishments, it becomes necessary to combine comfort, adaptability, and control, with what is

used as the best and safest dressing. The following narrative of a case and the apparatus used in the treatment of it, and others of the same nature, may perhaps be suggestive:

T. K., three years old, child of a farmer, accidentally fell from a two-seated buggy while the vehicle was in motion, and occupied by four persons besides the little unfortunate. The hind wheel, rising from a rut six or eight inches deep, struck the child's thigh as high up as the upper third of the femur, and a severe injury was the result, of course.

I reached the patient's house about three hours after the occurrence, found the child crying violently, the left foot everted, and the seat of injury in a very much swollen and ecchymosed condition. Indeed, so much swollen were the parts that it was impossible to determine whether the fracture was of a simple or comminuted nature. After applying a temporary dressing, and ordering a lotion with lead-water and laudanum, the child was left in care of the parents, to be seen again next morning and a permanent dressing applied.

A ride of seven miles afforded time for thought, and visions of "Cowling's Aphorisms" and plaster of Paris dressing flitted through the mind. An extended modification of the common fracture-box suggested itself as the best apparatus for treating the individual case, and, accordingly, early next morning a mechanic was called on, a rude drawing made, and a box constructed, of which the annexed figure, with perhaps a little explanation, will convey the idea. Next morning found the swelling considerably subsided; a few whiffs of chloroform were administered, and a simple fracture of the upper third of the femur was diagnosed. The next step was to apply plaster of Paris dressing. This done, a soft bed quilt was folded and laid in the box referred to, and our boy deposited and secured therein, taking pains to pack the leg with cotton on the outside of the plaster of Paris dressing, to guard against eversion and inversion. The perineal band was used to prevent slipping down in the box, but applied only when the plaster was partly set, thus causing no inconvenience whatever.

In ten days the boy sat up in the box, which was set on two chairs before a window, and played with his toys, perfectly contented. Even from the first day, he was carried to any part of the house, as well as put to bed, always in his box. At the end of six weeks he was liberated, and removal of the dressing showed good union; no shortening; the foot at a natural angle, and but slight bowing of the bone. The dressings were changed

DESCRIPTION OF BOX.

A is a plain board, even with the patient's head at its wide end, and extending six or eight inches beyond the foot at the other end, for the purpose of extension. *B* is a gate extending from the axilla to the foot end of *A*, to which it is attached with hinges; being perforated with the holes near the upper edge, for the purpose of securing the patient by means of strips of muslin passed to corresponding holes in gate *D*. *C*, also a gate on hinges, and perforated correspondingly with that part of *B* opposite. *D*, a gate on hinges, extending from axilla to offset at *E*, perforated to range with *B* on opposite side. *E*, aperture for chamber vessel. *F*, screw-eye for perineal band. *G*, pulley or spool on wire passed from *B* to *C* for cord with weight. A foot-board, *X*, may or may not be used. The apparatus is best made of poplar wood, as it holds screws better than other light woods.

three times during the treatment; the limb being carefully sponged with lukewarm water each time. It need hardly be mentioned that the uninjured leg was perfectly unconfined, being of course favored with freedom of motion only in so far as the recumbent position and the general situation might allow.

Now, the advantages of such an apparatus are:

1. Simplicity and ease of construction.
2. The persons in attendance can move the patient without risk of displacement of the fractured parts, thus overcoming the monotony of close confinement.
3. The patient can be laid on either side, and thus gain the benefit of change of position and prevent bed-sores.
4. The patient can attend to calls of nature without removing the box or using a bed-pan.

HOSPITAL REPORTS.

BELLEVUE HOSPITAL, JANUARY 5, 1884.

Reported by J. H. WOODWARD, M. D.

(Continued from page 268.)

Case 2. Gun-shot Wound of Thorax—Non-penetrating.

Alexander K—, aged twenty-nine years, admitted to Ward 9, December 21, 1883.

A short time before his admission to the hospital the patient had been shot in his chest. The wound of entrance was found two inches below the right nipple. Another wound was discovered in the areola of the left nipple, through which, the patient stated, some physician had extracted the ball. This wound had been closed with a suture of coarse silk, which was removed at once. After the patient reached the ward, his wound was not probed. There were no signs of injury

to the thoracic viscera. Patient's general condition good.

The wounds of entrance and of exit and their vicinity were washed with $\frac{1}{2000}$ solution of corrosive sublimate. A short drainage tube was placed in the wound of entrance, but none could be passed into the wound of exit without doing some violence to the tissues, and that wound was not drained. Both wounds were finally syringed with the solution of corrosive sublimate; and iodoform was then dusted upon them. Carbolized gauze and borated cotton composed the dressing.

December 22. No temperature. No chest symptoms. Learned that the bullet was a thirty-eight calibre.

December 24. Renewed the dressing, under irrigation with the sublimate solution. Discharge small in amount. General condition normal.

December 26. Removed the drainage tube. No tenderness along the track of the ball. Redressed as before.

December 28. The wound has healed perfectly. A small superficial ulcer remains at the wound of entrance. Covered that with rubber plaster, and discharged the patient cured.

Before giving the details of the following cases of abscess, it will be advisable to describe the surgical treatment which they received, for they were all managed in the same general way. In the first place, the region where the incisions were to be made was shaved and scrubbed with soap and water. It was then washed with ether and a five per cent. solution of carbolic acid; and finally, it was irrigated with a $\frac{1}{2000}$ solution of corrosive sublimate in water. The hands of the operator were cleansed and disinfected with carbolic acid. The syringes and instruments had been rendered thoroughly aseptic, and the drainage tubing had been soaking in $\frac{1}{20}$ carbolic solution for weeks. After the irrigation had been begun, the abscess was opened and the wound was constantly irrigated until iodoform had been sprinkled upon it.

Antiseptic precautions were as carefully observed as if the case were one of amputation through the thigh.

Case 1. Isaac H., age 34, admitted to Ward 8, October 11, 1883.

Patient states that his trouble began three months ago, when he received a blow on the left side of his face. His neck began to swell soon after the injury, and became red and painful. He applied poultices. Examination on admission revealed a large fluctuating tumor of the left side of patient's face and neck. Temperature not taken.

October 12. An incision was made about two inches above the clavicle, at the most dependent part of the abscess, penetrating the deep cervical fascia. Pus in large amount flowed from this wound. The abscess was not washed out. A large rubber drain was passed into the abscess cavity. Iodoform, mineral wool, and borated cotton, comprised the dressing.

October 13. Redressed under the irrigator. The mineral wool had failed to absorb the pus. Iodoform, carbolized gauze, and borated cotton, were used for the dressings.

October 16. Drainage tube removed. Induration much diminished. Redressed as before.

October 18. Removed the dressing and found that there remained only a small ulcer. That was dressed with iodoform and rubber plaster.

October 23. Patient discharged cured.

Case 2. Bernard A., 29 years. Admitted to Ward 10, November 24, 1883.

One week before admission the left side of patient's face began to swell. The swelling was painful, and during the last twenty-four hours patient had suffered from dyspnoea and dysphagia.

November 25. The abscess was opened and a rubber drainage tube inserted. A dressing of iodoform, carbolized gauze, and borated cotton, was applied.

November 27. Redressed the case as before.

December 1. Removed the tube and dressed the case as before.

December 8. Discharged the patient cured.

Case 3. Levi S., admitted to ward 10, December 27, 1883.

No history. He presents a large, red, indurated and fluctuating swelling of the left side of his face and neck. Temperature 102.

December 28. Opened the abscess, inserted a drainage tube, and dressed with iodoform, carbolized gauze, and a saw-dust bag, which had been rendered antiseptic with a solution of carbolic acid in alcohol, $\frac{1}{8}$.

December 30. Redressed. The saw-dust had not possessed any special advantages over the carbolized gauze as an absorbent. Drainage tube removed. Dressed with iodoform, carbolized gauze, and borated cotton.

January 1. Redressed. No discharge. Iodoform and rubber plaster.

January 8. Discharged cured.

Case 4. Patrick L., 47 years, admitted to Ward 10, January 15, 1884.

Patient states that about five weeks ago he had erysipelas in his right foot, and that about five weeks ago a painful, red swelling appeared on the right side of his neck. He was treated with salves, etc., prior to admission.

Examination reveals a red, fluctuating swelling of immense size, on the right side of patient's neck. The swelling begins below the clavicle in front, and extends to the inferior angle of the scapula behind. Patient is very weak, has a high fever, and his skin is wet with a clammy perspiration.

The abscess was opened at a point behind, over the spine of the scapula. The wound was a pretty deep one. Through it about thirty-two ounces of pus flowed, and the abscess was considerably diminished in size. The integument about the clavicular region was quite thin, but it was deemed advisable to allow the abscess to drain through the opening in the back. A large rubber tube was inserted into the abscess cavity. Iodoform, carbolized gauze wet in $\frac{1}{40}$ carbolic solution, and borated cotton, composed the dressing, which was large and thick. It was held in position by carbolized bandages, and over them a rubber bandage was passed to prevent the dressing from slipping. Ordered whisky $\mathfrak{z}$ ss, quiniæ sulph. gr. iij, and tr. ferri chloridi gtt. x.; q. 4 h., day and night.

January 16. Pus has appeared through the dressings. Re-dressed the case under the irrigator. The first dressing was saturated with pus. Iodoform, carbolized gauze, a large disin-

fected saw-dust bag, and borated cotton, comprised the dressing, which was secured by the rubber bandage. Ordered tr. digitalis gtt. x., t. i. d.

January 17. Temperature normal. Patient sweating profusely. Increased the whiskey to $\frac{3}{4}$ j. t. i. d. Opened his bowels with calomel.

January 19. Re-dressed the case as before, and found the dressing saturated with pus. The saw-dust bag had not absorbed the discharges so well as the carbolized gauze. Regular dressing of iodoform, carbolized gauze, and borated cotton applied. Ordered aromatic sulph. acid, gtt. xv., q. 4 h., to check profuse perspiration.

January 20. Patient is better; sweating less profusely.

January 21. Had temporary retention of urine this morning. Increased the dose of the aromatic sulphuric acid to gtt. xxx., and added tr. belladonna gtt. v., t. i. d.

January 22. Discharge through the dressing. Washed the abscess cavity thoroughly with solution of bichloride of mercury $\frac{1}{1000}$, until the water came away clear. Inserted a smaller drain, and dressed the case as before.

January 23. Discharge of serum through the dressing this morning. The soiled spot was dusted with iodoform and covered with borated cotton.

January 29. Removed the drainage-tube, and redressed the case as before, omitting the rubber bandage.

February 1. The abscess had healed completely, and requires no further attention.

Case 4. John D., age 6 years, admitted to Ward 7 on December 31, 1883.

Patient presented a large fluctuating swelling over his trachea. This swelling had begun three days earlier, and had increased rapidly in size until it was quite large. An incision was made over the upper part of the sternum, through the skin and superficial fascia. Through this about eight ounces of curdy pus flowed. A rubber drain was placed in the wound, and the usual antiseptic dressing was then applied.

January 1. Redressed the case as before.

January 4. Redressed again as before. Ordered syr. ferri iodidi and cod-liver oil.

January 10. The abscess has entirely healed, and patient is in much better condition than when admitted. He was under observation for one week longer, but no sign of return of suppuration in his neck having appeared, he was discharged cured.

Case 5. Susie H., aged nineteen months.

The mother stated that the patient had been sick for five weeks, and had been treated for malaria during that period. She had noticed a short time before she brought the child to the hospital that the patient was very tender about the left lumbar region. When presented, the patient was pale and anæmic; and in the left lumbar region there was a tense swelling, in which fluctuation was detected after careful examination. A hypodermic needle was passed into the tumor and the presence of pus demonstrated.

The abscess was opened at once and a large quantity of healthy pus liberated. A rubber drain was used and the usual dressing of iodoform, carbolized gauze, and borated cotton applied.

December 15 and 17. Case dressed.

December 20. The tube was removed.

The case was discharged cured December 28.

Case 6. Mary H., aged twenty-two years, admitted January 7, 1884.

Patient says that her child died three weeks ago, and that soon after her right breast became swollen, red, and painful. She poulticed it. When admitted, her breast was red, indurated, enlarged, and painful. The presence of pus was determined by the introduction of a hypodermic needle. The abscess was situated in the glandular structure.

January 9. An incision was made on the under surface of the breast and carried carefully through the skin and peri-glandular structure until pus was detected. This wound opened a cavity in the substance of the gland, containing about six ounces of pus. A second abscess was located with the hypodermic syringe, and it was opened in a similar manner. This abscess was above the plane of the nipple in the glandular tissue, and contained about eight ounces of pus. The septum between the two abscesses was one-fourth of an inch in thickness; and, although it was deemed desirable to drain the abscess through the lower wound, if possible, the danger of hemorrhage caused the operator to refrain from puncturing the septum. Both cavities were thoroughly washed with $\frac{1}{1000}$ solution of corrosive sublimate. A rubber drain was inserted into each, and iodoform was sprinkled upon the wounds. A large dressing of carbolized gauze wet in $\frac{1}{10}$ carbolic solution, and borated cotton, was applied; and its margins were secured by means of a rubber bandage in addition to the ordinary bandaging. In the evening she had a temperature of $103\frac{1}{2}^{\circ}$. But her temperature fell to normal within an hour after the administration of liq. morphine U. S. P., $\frac{3}{4}$ j.

January 10. Redressed under irrigation. No pus in the dressing. Removed the tube from the lower abscess cavity, and substituted a small tube for the large tube in the upper abscess. Applied the same antiseptic dressing.

January 15. Redressed the case and shortened the tube.

January 18. Redressed the case again and removed the tube. There was no induration about the breast. Patient is allowed to go about the ward.

January 22. The case has healed throughout, with the exception of two small superficial ulcers. There is no induration at any point. The ulcers healed rapidly, and the patient was discharged cured, having been under observation a number of days after the abscesses had healed. The scars were the only evidence that she had ever suffered from disease of the breast.

Chancroids and Bubo—Extirpation of the Inguinal Glands.

Lydia B., age 17, single. Admitted October 22, 1883. When admitted, the patient had large chancroidal ulcers at the posterior commissure of the vulva, and on the labium minorum. The lymphatic glands of the left inguinal region were already enlarged, tender, and painful. The chancroids were canterized with fuming nitric acid and dusted with iodoform. Tincture of

iodine was painted upon the bubo. Ordered two carbolyzed vaginal douches per diem.

November 2. The chancreoids have been cauterized every second day since the last note, with fuming nitric acid, and iodoform has been dusted upon them twice daily. The ulcers are healing, but the bubo is enlarging and suppuration is impending. Substituted for the tr. iodini:

R. Unguent iodini comp.

Unguent belladonna,

aa $\bar{3}$ ss.

S.—To be applied t. i. d.

November 7. Continued the same treatment until to-day. Instead of nitric acid, a solution of carbolic acid one part, in glycerine four parts, is used to cauterize the chancreoids. They are dusted with iodoform as before. The glycerine and carbolic acid are applied once every day.

November 13. The chancreoids are healing satisfactorily. The bubo is increasing. Applied sponge compression to the bubo.

November 16. The bubo is red and very large. It was aspirated with a hypodermic syringe, and pus withdrawn. Fifteen minims of pure carbolic acid were injected at the site of the suppuration.

November 17. Injected $\frac{1}{2}$ gr. of bichloride of mercury and five minims of carbolic acid in glycerine q. s. into various portions of the bubo. The remaining treatment is the same as before.

November 18, 19, and 20. Same treatment continued.

November 21. Aspirated $\bar{3}$ ij. of pus from the bubo, and injected $\frac{1}{2}$ solution of corrosive sublimate. This treatment was repeated, with some apparent improvement in the bubo.

November 27. Injected iodoform gr. xv. into the tumor.

November 29. Repeated the injection of iodoform.

December 1. The bubo is very large, and there are several points of fluctuation. The chancreoids are nearly healed. They are dusted with iodoform twice a day. Stopped all treatment of the bubo by injections, but applied ice to limit the inflammation as much as possible.

December 8. Chancreoids have healed.

December 10. Anesthetized the patient, and Dr. McBurney operated upon the bubo. But before the operation was begun, both inguinal regions and the mons veneris were shaved and scrubbed with soap and water. The left groin was then washed thoroughly with solution of bichloride of mercury $\frac{1}{2000}$. The operation was then begun, and the wound was frequently irrigated with the bichloride solution. It is unnecessary to state, perhaps, that every detail in the antiseptic management of the case was carefully attended to. During the operation several abscesses were opened, and the wound was contaminated with pus. When the glands had been removed, there remained a wound five inches long by three inches broad, which extended down to the fascia covering the deep blood-vessels. This wound was closed with catgut continuous sutures, and a small rubber drain was used to carry off the serous discharge. Iodoform and protectives were applied to the wound, and a dressing composed of carbolyzed gauze and borated cotton were fastened upon the groin by carbolyzed bandages. A rubber bandage was passed over all, to hold the dress-

ing securely in position. The patient was put to bed with the thigh semi-flexed upon her abdomen.

December 17. Changed the dressing for the first time to-day. The wound had united by primary union throughout, excepting at two or three points where there was superficial sloughing of the skin, due to tension. Shortened the drain. Redressed as before.

December 26. Changed the dressing for the second time. The wound is perfectly solid throughout. A small sinus only remains where the drainage tube passed. Inserted a short tube into it to keep the mouth open. Balsam of Peru, carbolyzed gauze, and borated cotton.

January 3. Removed the dressing and found the case had healed perfectly. During the progress of this case, the patient had had no febrile movement after the second day, and her temperature never rose to 101° at any time. The scar is narrow and in the fold of the groin, and is scarcely noticeable. It should be stated that throughout the entire management of the wound in this case the strictest antiseptic precautions were observed.

MEDICAL SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting December 5, 1883.

Dr. Charles W. Dulles, Surgical Registrar to the Hospital of the University of Pennsylvania, read a paper entitled,

Criticisms on the Specific Theory of Hydrophobia,

Nearly two years ago I had the painful experience of being summoned one day to take charge of a boy who was suffering with what is called hydrophobia. The unfortunate patient was under my care and observation less than twelve hours, when he died. The horrors of that day can only be understood by those who have had a similar experience. To stand in the presence of such distressing psychical disturbance, to see death advancing relentlessly, to feel that science furnishes no satisfactory explanation of the nature of the disorder, and offers no trustworthy remedy for its treatment—this was a trial of mind which intensified the weariness of body which the circumstances necessarily entailed. The details of the case were read before the West Philadelphia Medical Society, and are recorded in the *Medical News*, May 27, 1882. There can be found all the points which at the time most impressed me. There, too, are recorded the theoretical and practical notions in regard to hydrophobia which I had at that time. Later, on May 23, 1883, I read before the Philadelphia County Medical Society a paper entitled "Remarks on Hydrophobia," which was published in the *Philadelphia Medical Times*, August 11, 1883. In this are set down some of the conclusions which I had reached after more than a year's study of the literature of the subject. The point aimed at in that communication was to attract the attention of those who heard me to the extremely unsatisfactory condition of our knowledge in regard to this disorder, and to lodge in their minds the sus-

picion that the views so ordinarily held, and so positively stated in most of the text-books, are not as clearly established as most people believe. In concluding the discussion which followed in the Society, I stated all I wished to, at that time, of my own convictions, in the expression that "but little of the evidence upon which it (the commonly accepted theory of hydrophobia) rests, can be regarded as having an accuracy and reliability commensurate with the delicateness and gravity of the questions at issue." Since then I have continued my investigations, and the wider their extent has grown the firmer has become my belief that this statement was the very mildest that could have been used without sacrificing the truth. But I have learned by reading, and by experience, that those who differ from the majority are in danger of being treated to a certain amount of disdain, for their inability to accept as evidence what to others seems acceptable enough. For example, Dr. Parry, in his interesting work on *Cases of Tetanus and Rabies Contagiosa*, published in London, 1814, indicates his sentiments as follows: "It was formerly doubted whether any such disease as canine hydrophobia existed; and I have heard that the question was once solemnly debated in a society, which, after a long discussion, determined it in the negative by a majority of voices. The existence of the giraffe or camelopardalis, was long denied by the moderns, not only notwithstanding the accounts given of it by the ancients, and its delineation on the Prænestine pavement, but after its skin was actually to be seen dried and stuffed in a Dutch museum. We are told of a king of Siam, who, after he had heard with patient attention certain wonders from an European ambassador, and was at last informed by him that in this country, at certain seasons of the year, water became solid, and was capable not only of being cut or broken, but of admitting his majesty and his whole court to walk over it without wetting their feet, flew into a violent passion, exclaiming: "For a long while, notwithstanding the prodigies you have related to me, I thought you were an honest man; but now I am sure that you are an impudent liar." In this story, the intimation that our knowledge about hydrophobia has reached the "dried-and-stuffed" stage goes well with the other intimation, that the skeptics in regard to it are in the state of ignorance comparable to that of the king of Siam.

Later than Dr. Parry, but still in this century, Dr. Copland set the stamp of his learning on the doubters thus: "The supposition lately published that there is no such specific disease as rabies, and that it is merely the result of mental anxiety, etc., is only one of the absurdities thrown up on the surface of medical doctrine, and hardly deserves mention, and much less, serious refutation."

But scientific questions are not settled in this summary way, nor has the fear of being thought singular ever long deterred men from asserting what they had come to hold as convictions. That which has been branded as an absurdity has, over and over again in the history of the world, come to be established as a fact; and the same may yet be accomplished for the opinion of those who deny the specific nature of rabies or hydrophobia. One thing is sure, viz., that the attitude of severe

criticism seems to offer the only hope for the solution of the riddle of hydrophobia; since, in more than two thousand years, the acceptance and repetition of authoritative opinions has failed to furnish a theory which does not fly in the face of all analogy, or a practice which holds out a reasonable hope of saving a single life. Such is the real state of knowledge in regard to hydrophobia. The theories as to its nature are contradictory and illogical, the teachings as to its treatment are without the slightest hope of success. In regard to both, the ablest men who have discussed it occasionally or systematically are in irreconcilable opposition. While some hold to certain modes of communication, others strenuously deny them. While some admit its spontaneous origin, others will not admit it for a moment. While some think the virus is to be found in the saliva, the blood, the bronchial mucus, the milk, the flesh of rabid animals, others limit it to the first of these alone. In regard to the period of incubation, the widest divergence of opinion exists. The range is from one day to forty years, and no one seems to have been able to fix a limit to either its shortness or its length. Equal contradiction meets the gaze when one turns to the matter of treatment. From the throwing into a fish-pond, as practiced by Celsus, to the inhalation of oxygen, as recently practiced by Drs. Schmidt and Zebeden, there is a variety of methods which demonstrates how utterly every attempt to find a specific has lacked the guidance of any accurate idea as to the nature of the disorder. To almost any statement of men whose names are highly respected in medicine, may be opposed the most positive and contradictory statements of others equally respected. Virchow admits (*Handb. d. Spec. Path. und Therap.* "Wuthkrankheiten und Wasserscheu") that hydrophobia may be communicated by means of weapons used to kill mad dogs with, and by blood-letting and scarifying instruments—a belief which, but for Virchow's adherence to it, would be correctly designated as obsolete, and which is entirely unworthy of acceptance. Bollinger, a distinguished veterinarian, admits (Ziemssen's *Cyclop.*, art. "Hydrophobia,") the possibility of infection by the migrations of animal parasites, such as fleas and lice.*

The late Dr. Geo. B. Wood admitted the possibility of hydrophobia being caused by the bite of birds, and explains why this does not often occur, as owing to the fact that these animals, like horses, asses, and oxen, do not usually bite (*Practice of Medicine*, vol. i., art. "Hydrophobia"). In view of these facts, it will not seem so remarkable that Savages believed the eyes of hydrophobic patients to shine at night like those of cats, or that he should explain this on "meaque de hydrophobia theoria, quæ admittit in hoc morbo fluidum illud in phosphoricam activitatem exaltatum." (*Nosologia Methodica: Vesanior*, vol. i., p. 232.) Nor can one wonder that Mead, about

*This curious idea is founded upon a reference, which, when I hunted it up, I found to be a pure assumption of Dr. M'Crae (*Lancet*, March 23, 1872, p. 420) that the occurrence of smallpox thirteen miles northeast from Melbourne, where it was also present, was to be accounted for only on the supposition that it was conveyed by flies. It has been interesting to observe, in my own investigations, how this supposition of Dr. M'Crae has grown to a statement of an established fact, as it has been quoted by foreign writers.

a hundred years ago, should have said, "The influence of the moon in these cases, I am convinced, is of some weight." (*Medical Works*, art. "Hydrophobia," p. 62.)

But, to return to modern times, what shall one think of the attempt of Doléris, the author of the, in many respects, admirable article on this subject in the *Nouveau Dictionnaire de Médecine et de Chirurgie* (1881), to explain the assertion of the occurrence of spontaneous cases by saying that the disorder may be acquired from germs distributed in the air and earth, like "charbon"? Or, how shall we consider the willingness of Sir Thomas Watson (*Nineteenth Century Review*, December, 1877), to accept the occurrence of hydrophobia by the infection of sucklings through the medium of mother's milk, or his statement that the disorder does not occur in Constantinople or Africa?—in both which places it does occur.

But I do not wish to make too much of this aspect of the literature of hydrophobia. I wish to call your attention to the cause of the uncertainties which prevail in regard to it. This is, in my opinion, easy to point out. It is the too great readiness to accept any sort of testimony which may be offered as bearing upon the subject. This fault is to be found in almost all the works treating of hydrophobia, from the earliest ages to the present time. This led Pliny to father such absurdities as the following: "There is a small worm in a dog's tongue, known as 'lytta' to the Greeks; if this is removed from the animal while a pup, it will never become mad or lose its appetite. This worm, after being carried thrice round a fire, is given to persons who have been bitten by a mad dog to prevent them from becoming mad. This madness, too, is prevented by eating a cock's brains; but the virtue of these brains lasts for one year only, and no more." And, again, "So virulent is the poison of the mad dog, that its very urine, even if trod upon, is injurious, more particularly if the person has any ulcerous sores about him. The proper remedy in such a case is to apply horse-dung, sprinkled with vinegar, and warmed in a fig." (Pliny, *Natural History*, book xxix., chap. 32. Trans. by Bostock and Riley.) This same too easy acceptance of testimony led such a writer as Dr. Samuel Bardsley, in 1807, to accept the statement that hydrophobia could be communicated by the mere application of the saliva to the unbroken skin, and to cite with apparent approval a story of a man who had hydrophobia from kissing a mad dog previous to its being langed. (Samuel Argent Bardsley, *Med. Reports*, London, 1807.) And, most recently, it has led Bollinger, already referred to, to attribute the disorder to drinking the milk of an affected animal, and to the act of coitus. (*Ziemssen's Cyclopadia*, 1875.) While Mr. Williams, in his valuable work on *Veterinary Medicine*, 3d ed., 1882, says that rabies can be communicated through a "thin epidermis without wound or abrasion."

These citations illustrate the most remarkable feature of the literature of hydrophobia. It would seem as if when once the mind has accepted a theory which contradicts all experience in other and fairly well-understood diseases, it loses the ability to distinguish good evidence from bad. A striking illustration of this is furnished by Dr. Dolan, in his otherwise capital book on

Hydrophobia or Rabies. In his second chapter this writer calls attention in detail to the rules laid down by Dr. Abercrombie, in his *Inquiries concerning the Intellectual Powers and the Investigations of Truth*. These warn against the following fallacies: 1. Receiving as facts statements which are not facts, but opinions. 2. Receiving as facts statements which only assume the relation of facts. 3. Receiving as facts general statements, or the generalization of facts. Dr. Dolan then says: "Some writers, for instance, have maintained with much confidence that a particular state of rigidity of some of the limbs is distinctly characteristic of *ramollissement* of the brain. But further observation has shown that the disease may exist without this symptom, and that this condition of the limbs may appear in connection with other diseases. This observation of facts was in so far correct that this state of limbs does very often accompany *ramollissement* of the brain: the error consisted in giving it as a general fact, or a fact applicable to all cases of *ramollissement*, which is without foundation. Yet such statements, when brought forward with confidence, are often received as facts and rested upon as established principles; and then the facts by which their fallacy might be detected are apt to be overlooked or forgotten." To this reference to the commonest sources of fallacy Dr. Dolan adds: "We are arming our readers against ourselves." And yet he goes on, apparently with his eyes wide open, to reproduce the fault he has just pointed out in speaking of *ramollissement*, accepting statements which ought not to be entertained for a moment in the discussion of so grave and delicate a subject, and admitting as genuine cases which are transparently spurious. I will give an example of this latter mistake, which illustrates several points at once. Dr. Dolan gives in his collection of cases, and, after sifting his material, stamps as true the following from Romberg's *Diseases of the Nervous System*:

"Case 74. Frederick L., male, æt. 6, bitten on the second finger of the left hand by a dog which had already bitten several other children. Result and time of attack, three months; fatal third day.

"*Treatment*.—A few of the dog's hairs had been cut off to place upon the wound, which in eight days was completely healed. The treatment consisted in taking twelve ounces of blood from the arm, scarifying and applying cantharides ointment to the cicatrix, rubbing in a scruple of mercurial ointment into the inner surface of the left arm. Dr. Horn also visited the boy, and described his features as expressive of extreme anxiety, while his eyes told a tale of immeasurable misery. He implored that he might not be touched or bled again, as he desired nothing more than to be allowed perfect rest."

The post-mortem was made on the 4th of September, 1820, twenty-five hours after death. The smell of putrefaction was already developed. The muscles were dark red. The lungs were charged with blood. The larynx, the trachea and œsophagus were not abnormal in appearance. But, the record says, "the redness of the heart was remarkable, the arteries and veins on its surface looking as if they had been injected. The mitral and aortic valves presented a scarlet hue, the trabeculæ carneæ were darker than usual, the in-

ternal surface of the aorta was of a bright red hue as far as the arch; the blood contained in the vessels was dark and fluid; the inner surface of the stomach was as pale as that of the œsophagus. No morbid change was found in any other abdominal organ. At the urgent request of the parents, the head was not examined."

The history of this case as originally described in Romberg's book (*Nervous Diseases*, translation: London, 1853), taken together with the post-mortem appearances, seems to me to show it to have been one of acute endocarditis, probably septicæmic. But no such idea seems to have entered the heads of the physicians who attended it. As a case of hydrophobia, they went most heroically to work to treat it.

Picture to yourselves the scene. Think of that little child, only six years old, tested with the useless and dangerous tests of handwashing, and mirror, and with urine sprinkled on his skin—the former showing nothing, the latter causing a paroxysm. Think of his being bled, the cicatrix being scarified and blistered with cantharides, and mercurial ointment being rubbed into his arm. Then fancy him, when the doctors came at him after an interval, imploring only to be left in peace, whilst they, with grim determination, bled him again, and dosed him with calomel, after which—to quote Romberg literally—"death came to his relief."

In reporting this as a case of hydrophobia, Dr. Dolan has followed the opinion of Romberg, who when he recorded it had *never before seen a case*. But it strikes me as a very piteous illustration of the truth of what White said (*Doubts of Hydrophobia*, London, 1826,) of the course of many cases. He described the usual alarm, the fear of the patient, the suspicion of the doctor, the test with water, the melancholy conviction of doctor and patient, adding: "The patient and himself, therefore, will soon *make out a case*—the one dies, and the other publishes an account of his end." Does it seem unfair to apply such an expression to such a case as has just been cited? On the contrary, does not the history of the case indicate that general eminence in medical science gives no guarantee of infallibility when this vexed subject is approached?

I have selected an illustration of the point I wished to make, which should include two names well known and justly distinguished, because their very excellencies add force to the proof they furnish that the prepossession of a theory which at the outset demands a certain surrender of the judgment, will impair the freedom of the judgment at every subsequent step. Such it seems to me is the condition in which every believer in the specific nature of hydrophobia stands. The assumption of a specific virus which, and which alone, is the originator of the disease in any individual, compels its adherents to bend their judgment to accept the belief that there is a virus which behaves in a way contradictory to that of every other virus about which we have any positive knowledge. As Lorinser has said (*Wien. Med. Wochenschrift*, 1874): "We know very well the appearances produced, for example, by the bite of poisonous serpents, or by the poisoning of wounds with the poison of glanders, anthrax, syphilis, or cadaveric poison. There are, in general, always

the manifestations of more or less rapidly developed inflammation, and of further distribution of the poison through the lymphatics, veins and lymphatic glands, which organs then, in like manner, manifest similar inflammatory symptoms. Nothing of the kind do we see in wounds made by the bites of mad dogs," etc. And, again: "We know, in all pathology, not a single infective disease, which, in regard to the time and symptoms of development, bears the slightest resemblance to hydrophobia."

One might suppose that such a contradiction would lead observers to be constantly on the look-out to find some other way of explaining the phenomena of hydrophobia, and that everything that was presented as evidence in support of it would be subjected to the most rigid scrutiny. But the literature of the subject shows that the very opposite is the case. The *post hoc propter hoc* argument is the one which rules here. A careful perusal of a large number of recorded cases leaves the impression that they have not been studied with any idea that they might be something else than what they appeared to be. Though it is no secret that the dread of water is a symptom of a great variety of affections, one finds over and over again the ablest men resting a diagnosis on this which is acknowledged by most systematic writers to be the least reliable of its signs. Another thing which struck me in examining the records of cases is the readiness with which reporters, aware of the objection so often raised, of the effect of mental influence, accept the statements of friends or the silence of patients in regard to it as evidence that it does not exist. I will give an example of this. In the *Berliner Klin. Wochenschrift*, September 15, 1879, Dr. Findeisen reports a case of a man who died of hydrophobia, and who is positively stated not to have known that the dog that bit him was mad, or to suspect that he had hydrophobia, or connect his disease with the bite. Yet the record states that, on the second day of his disorder, he cried out that he had been bitten by the "poisonous (*giftiger*) dog," and was not crazy.

(To be continued.)

Lying-in Room Hints.

A very good article on this subject by Henry F. Walker is published in the *Med. Record*, February 23, 1884. The points which he wishes to emphasize are:

1. Examine every woman immediately after delivery, and if there is any laceration, even a trifling one, close at once with silk sutures.
2. Examine every woman when she begins to move about, and if there be displacement of any kind, anteversion, retroversion, or prolapsus, introduce a proper pessary, with the hope that its temporary use during the period of involution will establish a cure.
3. Examine at birth every male infant, and if the prepuce be so contracted or adherent that, with probe and pressure, the glans penis cannot be uncovered, operate by splitting the prepuce as far back as the corona with scissors or bistoury; the chosen time for operation, unless urgent symptoms present themselves, being the ninth day.

EDITORIAL DEPARTMENT.

PERISCOPE.

A Case of Actinomycosis. *following*

Dr. W. Knight Treves reports this case in the *Lancet*, January 19, 1884:-

P. C., aged 45, was admitted to hospital August 17, 1883, supposed to be suffering from a scrofulous affection of the glands of the neck. He is a muscular man with a good family history. His illness began sixteen months before admission, with inflammation about the neck and angles of the jaw, which however only kept him from work for two or three days. He has lived well, and never had cattle to look after. A lump by the angle of the jaw followed the inflammation, which was incised. Subsequently other swellings formed. Over the angle of the jaw, and in the posterior triangle of the neck were three ulcerated and fungating surfaces, those by the angle of the jaw being about one inch and that in the posterior triangle about two inches in diameter. There

were tumors over the collar bone, the second rib, and the fourth costal cartilage near the sternum, each of which was in a direct line, and had followed in regular order the one described as existing in the posterior triangle. These tumors resemble each other in appearance; they are smooth and evenly formed, and are in shape as nearly as possible a half a sphere; the upper one is two inches in diameter, the lower one an inch, and the middle one intermediate in size; they have an elastic, semi-fluctuating feel; the skin over the

upper one is thin, red, and evidently about to give way; the skin of the middle one is also discolored; that of the lowest is normal. To the right and left of these tumors are two nodules about the size of a marble, apparently the same thing in process of formation. The discharge was thin and serous, and contained minute yellowish masses, and disintegrated tissue, and had a peculiarly offensive and sour smell. The patient declined operative interference. He remained in the hospital till December 7, the progress of the case being gradual loss of flesh, formation of lumps on the other side of the neck, and in the axilla. The three tumors described became broken down, and he presented before his discharge the appearance given in the woodcut, which is from a photograph. The appearance of these tumors resembled nothing that I had ever seen before. The case was certainly not scrofulous, nor was it like any new growth with which I was familiar. I arrived at the conclusion that it was an example of the disease known as actinomycosis. This diagnosis was confirmed by the discovery under the microscope of bodies which I believed to resemble the fungus described as peculiar to this disease. So far as I can ascertain, this is the first case of actinomycosis described in this country.

Castration for Uterine Fibroids.

We learn from the *Edinburgh Med. Jour.*, January 1884, that at a meeting of the German Science Association, Wiedow, of Freiburg, opened a discussion on this subject. He suggested that the operation was now thought too little of, because at first it was taken up with too great enthusiasm, and tried in unsuitable cases. He collected 63 reported cases, of which 12 had been fatal. In one of Hegar's cases there was a temporary improvement after operation, lasting about six months, followed by increased growth and a return of the hemorrhage. The patient died a few months subsequently, when the tumor was found to be fibro-cystic and to contain purulent serum. In this case, as in a similar one reported by Schröder, the tumor was enormous (kolossal). For such cases the writer would give an unfavorable prognosis. Hegar had operated 21 times with 3 deaths. Of the 18 non-fatal cases 1 terminated as above, while in 17 the result of operation was very satisfactory. Sooner or later the menopause, with shrinking of the tumor, occurred. The writer then showed drawings of Hegar's cases before and after operation, and submitted 4 of the cases for examination. Freund, of Strassburg, reported 6 cases in which he had operated. All had lived, and in five there had been shrinking of the tumors and cessation of the bleeding. In 1 there had been no improvement. In this case the tumor was "kolossal." Hofmeier, of Berlin, asked what were the indications for castration as opposed to removal of the tumor. Hegar, of Freiburg, said that the size was not the only point that would guide one in answering

this question. As regards the danger of the two operations, he said that on an average that of castration was the lesser, though this was not invariably the case. He always had instruments at hand to remove the tumor if advisable, when he undertook castration for fibroids. If he found a well-developed pedicle, he removed the tumor. He regarded castration as a very efficient operation, and thought it should be recommended before the tumor had acquired great size. Kaltenbach, of Giessen, drew attention to the fact that occasionally the ovaries were situated on the apparent posterior aspect of the tumor, and that thus great difficulty might be occasioned. He reported two successful and satisfactory cases of his own, but drew attention to the fact that removal of the ovaries did not always result in the menopause. Badleiner referred to two cases where decided diminution of the tumors occurred after the natural menopause. Müller, of Berne, had operated in 6 cases, with 1 death and 1 uncompleted operation. In the remaining 4 the result was satisfactory. He regarded castration merely as a resource, and looked on extirpation of the tumor as the ideal operation. Hegar remarked that he had seen fibroids suddenly begin to grow and become cystic after the natural menopause, even in cases where there had occurred some shrinking, just as had been mentioned in the discussion as having followed the anticipated menopause. In all those cases the tumors had been very large, and he would therefore regard the prognosis of castration for very large tumors as doubtful.

Neuralgia of Bone.

In the *London Med. Times*, January 19, 1884, Dr. J. Matthews Duncan says:

When a bone of the pelvis has been injured, the part, sometimes after complete recovery so far as manipulative examination is concerned, retains a morbid sensitiveness or weakness. It is not swollen; but it is liable to ache severely or be painful. Cases of this kind in bones of the limbs I have known to be successfully treated by laying the bone bare by knife, raising the periosteum, and gouging or chiselling off the surface of the affected part. In my cases I have not resorted to this, and I may best and most briefly tell you all I know of the matter by giving a few details of two.

A fine, healthy young woman had a first labor, managed by a skillful accoucheur, natural in all respects, except that delivery was completed by short forceps. At the time of delivery nothing special was noted as to wounding; but the patient felt a deal of pain in the private parts, on the left side, during all her recovery. She got up, however, and was well and strong; but as soon as she began to walk, the pain in the left labium recurred, and was increased in severity as she increased the use of her legs. The pain was now ascribed to weakness, now to falling of the womb, now to ulceration, and was treated accordingly, but with no good effect. Careful local investigation discovered the labium to be internally cleft, and the deepest part of the cleft quite healed, healthy looking, but adhering to the descending ramus of the pubes. The bone was scarcely tender, but whenever it was touched, the patient at

once, and again in subsequent examinations, declared that that, and that alone, was the seat of pain. The bone was occasionally tender after great exertion, as in dancing: it was always and exclusively the seat of the aching pain. The labium had been cut by the anterior margin of the left blade of the forceps, and healing had taken place with adhesion of the cervix to the adjacent bone. Complete satisfaction as to the seat and nature of the disease was half the cure. Avoidance of long walks and of much dancing, hot bathing at bedtime, tonics, iodide of potassium, were all used, and did not bring quick relief. It was not till these cures had been continued more than a year that the whole matter was forgotten. Now she never feels it.

A middle-aged woman, a clergyman's wife, was thrown out of a little pony phaeton, and fell on her sacrum. After the accident she had continued pain in it for a long time; and the pain recurred after intervals of health varying in length. When it came, she felt the part to be a little tender, but not swollen. Latterly, after some years, she was led to believe that now her suffering was not from the injury, but from disease of the womb. Then she consulted me, and it was very easy to make out that the pain was in the bone, exactly where the injury had been inflicted. There was no uterine disease, and the conclusion was inevitable that the case was one of neuralgia consequent on mechanical injury. With assurance on this point she was quite satisfied, and went away with some directions as to treatment when the aching came on.

Perhaps this disease should be called chronic ostitis, not neuralgia: I do not here attempt to decide.

Antiseptic Inhalation.

Dr. L. E. K. Shuttleworth writes to the *Lancet*, January 5, 1884, from San Remo, Italy, as follows: In the present state of our knowledge of the bacilli of tubercle and of the action or inaction of antiseptic inhalations, I believe all observations are of value to the profession. I therefore venture to send you a few lines, recording my experience of the action of antiseptic inhalations as ordinarily used, from observations taken, thanks to the kindness of my colleagues here, Dr. Daubeny and Dr. Freeman, in typical cases under their care, as well as under my own care, and also a few lines descriptive of the results of experiments I have made on the vaporization of carbolic acid and a description and drawing of an apparatus I have had constructed, by means of which I believe carbolic acid and other disinfectants may be much more thoroughly vaporized and inhaled than by any ordinary method.

During last winter I examined constantly the sputa of patients under the care of Drs. Daubeny, Freeman, and myself, in which the bacilli had been demonstrated, and I was much struck with the fact that in the great majority of cases where carbolic inhalations were used with an oro-nasal inhaler in sufficient quantity, a great diminution in the number of bacilli took place; and that, though from time to time fresh crops appeared, these, when the inhalations were continued, regularly but gradually diminished both in frequency

of occurrence and in the relative number of bacilli. But I was also struck with the difficulty in persuading patients to inhale efficiently—i. e., to apply the inhaler so as to exclude all uncarbolized air, and in many cases also they did not at first inhale freely, and the carbolic acid, being not very readily vaporized, is not taken up from an ordinary inhaler unless the respirations are fairly deep and strong. I therefore considered, How can carbolic acid be effectually vaporized? And during the summer months made the following experiments, with the kind assistance of Mr. Gurnell, the well-known chemist at Ryde. I exposed fifteen minims of carbolic acid to the air of an ordinary room in a watch glass; at the end of twenty-four hours the weight was not perceptibly altered. Next I exposed fifteen minims in a watch glass to a heat kept as nearly as possible to 170°F. , in a water oven; the result being that at the expiration of five hours, during which the temperature had never exceeded 170° , or been below 150° , no trace of carbolic acid could be found in the watch glass. Next I tried with a temperature ranging from 200° to 212°F. , and found my carbolic acid had entirely disappeared in two hours. My next idea was to pass all the air inspired (1) through eight or nine feet of metal tubing heated to any temperature required; (2) through the carbolic acid also heated, and (3) through a proper oro-nasal mouthpiece. For this purpose I had an instrument constructed consisting of nine feet of metal tubing coiled inside a tin boiler, the afferent end being open to the air, and the efferent expanded into a small chamber, closed by a hollow plug of metal, in the interior of which tow could be placed to receive the carbolic or other disinfectant, and which was connected with an ordinary oro-nasal mouthpiece properly padded by a large india rubber tube. I then placed 13 grains of carbolic acid on 8 grains of dry tow, making a total weight of 21 grains, and placed this in the hollow plug. After ten minutes' inhalation the total weight was reduced to 13 grains; after twenty minutes, including the time occupied with the first weighing, to 8 grains +, after thirty minutes to 8 grains —, showing, as I believe, that the total amount of carbolic acid was completely vaporized in about twenty minutes, and from my sensations of tingling lips, sore nose and throat, pain in the chest, and slight vertigo, with exhilaration of spirits, I believe faster than desirable for ordinary inhalation. The temperature of the water in the boiler ranges from 170° at the commencement to 198°F. at the termination; a slightly lower temperature causes the vaporization of the carbolic to be more gradual, and I venture to claim for this system that by it carbolic acid and many other antiseptics can be perfectly vaporized in hot dry air, the heat and dryness being of themselves beneficial, and that the apparatus can be used at the patient's own home, and is not expensive. Mine, made by a working tinsmith, cost less than five dollars.

A, Cylindrical boiler, made of tin, 8 in. by 6 in., supported by three legs, closed except at S, over a spirit-lamp (B). C, The afferent end of the air tube, which enters the boiler at the side and is coiled round within it, 90 in. of metal tubing having an internal diameter of $\frac{1}{2}$ in., being disposed in the cylinder. D, The efferent extremity of the tube, ending in a small cylindrical expansion, which receives the hollow plug (E), having an internal diameter of $1\frac{1}{2}$ in., and a depth of 1 in., in which the dry tow to receive the antiseptic substance is placed, and which is connected with the mouthpiece (G) by an India rubber tube (F), having an internal diameter of $\frac{3}{4}$ in. and a length of 18 in. G, The mouthpiece, with three valves. I, A small one on each side to give exit to the expired air. H, A larger one to admit the heated antiseptic air and prevent the return of expired air. K, An India rubber air-pad round the mouthpiece, which covers both nose and mouth. L, L, Handles for lifting the cylinder. S, A small funnel, through which the boiler (A) is filled, and the thermometer (T) introduced. (The drawing is one-tenth the actual size of the apparatus.)

Electrolysis in the Treatment of Dracunculus.

Dr. Alexander S. Faulkner thus writes in the *Brit. Med. Jour.*, December 29, 1883:

O. L., a Hindu goldsmith from Kattyawar, aged 28, was admitted into the Civil Hospital, Aden, on July 25th last, suffering from the effects of the presence of four Guinea-worms in different parts of his body.

The patient, though a slight man, was fairly nourished, and his general constitution and functions did not seem much impaired. The different positions of the several worms were as follows; About the upper third of the outer aspect of the right leg, a worm had protruded about three inches; on the lower third of the outer side of the left thigh, another had also protruded to the extent of about two inches; on the dorsum of the left foot, he had a fistulous opening, indicating the site where a worm appeared, but was broken off in the patient's endeavors to extract it, but the remaining portion of the worm could be distinctly felt in the surrounding subcutaneous tissues; and on the back of the left hand, especially between the little and ring fingers, another worm could not only be felt, but its tortuous course was distinctly visible, but, so far, its presence caused no inflammation, and, consequently, there was no apparent indication of the site of its intended exit.

The patient had only been in Aden for three months, having previously resided at Kattyawar, in India (a district where this disease is of very

common occurrence). The first indication he noticed of his present condition was a "swelling" on the outer aspect of the left thigh, which resulted in an abscess, and subsequently burst, discharging a good deal of pus, and the head of a Guinea-worm. In trying, by forcible traction, to extract the latter, the worm naturally broke, its greater portion remaining within. Subsequently, other abscesses formed, in like manner, in different parts of his body, caused in each case by the presence of a Guinea-worm, all of which were treated by the patient by extracting only portions of a worm at a time. In this way, he stated, he had been suffering for the last five years.

On presenting himself for treatment at the Civil Hospital, I determined to try the experiment of applying galvanism to the protruded worms, an idea I have for some time wished to test practically. The result in this case was most encouraging and satisfactory. The patient held one pole of the battery in one of his hands, and the other I applied to the head of the worm which protruded from the patient's right leg; he at once distinctly felt the sensation of the worm "wriggling" within, which caused him slight pain. I left him for about an hour with my hospital assistant, with instructions that slight and gradual traction should be applied on the worm, and by these means, and in this short space of time, the whole worm was extracted entire. Afterwards, I applied the battery, as before, to the worm protruding from the patient's thigh; and, although the effects on this worm were not quite so satisfactory, still the result was very encouraging, as the entire worm was successfully extracted next day. Poulitices were applied over the fistulous opening on the foot and the patient's left hand—the situations of the two other worms. On July 30th four inches of a worm were extracted from the foot after the battery, and subsequently a poultice, had been applied. No other worm reappeared here, and the inflammation soon subsided. I therefore concluded that the whole of the remaining portion of the worm, which the patient had previously broken, had now come away.

On August 3d, about two inches of the worm on the patient's left hand appeared after the bursting of a small abscess. Galvanism was applied to this worm as in the former instances, and a poultice ordered. Galvanism was again applied on August 5th. The worm had protruded four inches, and was now six inches long. On August 6th the protruded portion of the worm was about twelve inches in length. The battery and poultice were applied, and in the evening the entire worm was extracted whole. There being now no signs of the presence of any other worms, the patient was discharged from the hospital.

Remarks.—The usual routine method of treatment in these cases is the application of poulitices over any inflammation caused by the presence of a Guinea-worm, and, when once the worm has appeared, means to prevent its re-entry into the body are resorted to, such as twisting the protruded worm round a small quill or other convenient substance, and gradually twisting the worm more and more each day till the whole is extracted, a decidedly lengthened and tedious procedure in most cases, and usually unsatisfactory in its results, as the worm is very apt to be

broken, and, if so, the general constitution of the patient suffers. The idea of applying counter-irritation to the worm itself to expedite its safe extraction in these cases, first struck me when perusing some notes (*Annual Medical Reports of the British Army*) by Surgeon Stewart, Bombay Medical Department, in which he stated he had tried the experiment of applying the sting of a scorpion to protruded worms; and my object in recording the above brief notes of my case is to bring to notice the very satisfactory results I obtained by far simpler and more convenient means of counter-irritation, viz., the application of galvanism to the worm. This, no doubt, has the effect of paralyzing the worm to such an extent that practically there is no resistance to its extraction so far as the worm itself is concerned, and its rapid and entire extraction is consequently made easy if only ordinary care be taken in handling the worm.

Although this mode of treatment is a novel one (so far as I am personally aware), still I feel that the successful result of the above case, obtained by its means, is sufficient in itself to warrant the hope that others more favorably situated than myself for meeting this disease will give it a fair trial, and record their results.

Protean Skin Affections in Children.

Before a recent meeting of the Academy of Medicine in Ireland, Dr. C. F. Moore read a paper detailing a protean skin affection. He stated that children were not infrequently attacked with a complication, assuming a resemblance to pruritus cutaneus of Hebra, prurigo, pemphigus, and, in some severe cases, pemphigus gangrenosus, or burnt holes of older authors. The diseases which in Dublin had been complicated with the foregoing in varying degrees of severity, were variella, scabies, insects, dentition, certain forms of rash, induced by inunction of irritating medicinal or domestic remedies, and, rarely, vaccination. The cases which had lately come under his notice were those of children whose ages varied from a few weeks to eight years. He did not think he had seen in this country a case of the disorder specially named prurigo by Hebra. Bad or unsuitable food tended strongly to the production of the disorder. The irritation caused by pediculi and other insects, and by clothing in a damp or uncleanly state, not uncommonly produced pruritus. Unhealthy surroundings, and a low condition of the child, or of its nurse, tended greatly to the production of the ailment which he wished to bring under notice. The treatment of these cases resolved itself into general and local—better sanitary condition, better food for the child, removal as far as possible of the cause of the irritation, thorough cleanliness, and, generally speaking, soothing applications; baths, with bran, or tar, or liquor carbonis detergens, etc.; mild alteratives, with suitable tonics; cod liver oil, or preparations of iron. In all cases inquiry should be made for the presence of intestinal worms, and the treatment suitable pursued. The affection, which seemed allied to prurigo, pruritus, and pemphigus, occurred in eight cases that were originated apparently by varicella; in four cases where scabies existed previously; in one case in which tallow had been used as a domestic remedy

by innunction; and another in which a very slight appearance of prurigo natis existed. The latter ailment was apparently increased after vaccination. The cases that had come under his notice had occurred almost invariably either in the cold spring or early winter. He did not refer to the many cases of pruritus and prurigo that he had seen in the adult and in youth. The affection noticed by Mr. Hutchinson, of London, as varicella prurigo, and regarded by Mr. Balmanno Squire rather as ecthyma or lichen urticatus, seemed to resemble cases which he had seen in Dublin, but which were of a very protean character, and did not generally assume the serious forms described by Mr. Hutchinson, or by Professor Hebra in describing the life-long character of the prurigo met with at Vienna.

Dr. H. C. Tweedy described the case of a boy aged sixteen, who had come under his observation, presenting the features of true prurigo, which he had had since childhood, and which resisted all treatment.

Dr. Duffey said Dr. Moore had described several skin affections, but had not specified the particular one which he considered now prevalent. It was a common thing to find eczema on the soles of the feet and the palms of the hands in infants.

Dr. Fitzpatrick did not believe that pure vaccine matter would produce skin disease in a healthy child.

Dr. Moore, in replying, was glad to find that Dr. Fitzpatrick's experience confirmed his own opinion that vaccination in itself was not a cause of skin disease.

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—The "Fifth biennial Report of the State Board of Health of Maryland" forms a volume of 275 pages, with a great deal of good and original matter in it. The report of the Secretary, Dr. C. W. Chancellor, surveys the whole field of action of the Board, and is full of suggestion. A number of valuable papers were read before the convention on subjects relating to public health, and are printed with the report. The volume can be had of the Secretary, Baltimore, Md.

—The "Thirtieth Report on the Births, Marriages, and Deaths in the State of Rhode Island" (for 1882) is a portly pamphlet of 178 pages, bristling with statistics, and presenting the vital records of the State with every desirable fullness and with most satisfactory clearness. It is a model volume of its kind. Those wishing it may address Chas. H. Fisher, M. D., State Registrar of Vital Statistics, and Secretary of the State Board of Health, 17 College street, Providence, R. I.

—A "Tribute to J. Marion Sims, M. D.," by Dr. W. O. Baldwin, Montgomery, Ala., is a com-

position full of appreciative views of the great gynæcologist's career.

—A striking paper was read by Dr. E. P. Howland, of Washington, D. C., before the American Association for the advancement of science, at Minneapolis, August 20, 1883. Its subject was "The Application of Nitrous Oxide and Air, or Nitrous Oxide and Oxygen, Under Pressure, to Produce Anæsthesia in Persons for Dental and Surgical Operations." He begins by saying: "From my own experiments and the practical operations made in Paris, I believe that the administration of nitrous oxide and air or nitrous oxide and oxygen, in condensed air chambers, will yet supersede the use of ether and chloroform in prolonged dental and surgical operations, as nitrous oxide has already superseded them in ordinary dental operations." The reasons he gives seem to us very conclusive.

—The fourth annual report of the Newark (N. J.) Eye and Ear Infirmary, indicates that it has grown to a position of great usefulness in that community.

—The Annual Announcement of the Cooper Medical College, San Francisco, shows that institution to be in a flourishing condition.

—*Godey's Lady Book* for March is a number upon which it would be hard to make any unfavorable comment. For some time past we have been watching with interest and pleasure the liberal policy which has been pursued by the present proprietors of this progressive magazine, and, from the evidence before us, we are now prepared to say that the editors of *Godey's* are bent upon placing the future record of the magazine on a higher plane than it has ever stood before.

—*Lippincott's Magazine* for March opens with an article on "The Berlin of To-Day," by Anna Maynard Butler, sketching the chief features, external and social, of the German capital, with illustrations, including a portrait of the Emperor and views of the old castle and Bismarck's palace. Quite a number of other excellent articles are included.

—The Tenth Annual Report of the Cincinnati Sanitarium has an excellent introduction from the pen of the Superintendent, Dr. Orpheus Everts. Among other matters, he says of venesection:

"Fifty years since, blood-letting was the first remedy suggested and employed by the medical profession in the treatment of nearly every form of disease. Not one physician of a thousand now bleeds a patient under any circumstance. The more intelligent and thoughtful, however, begin

to recognize the fact that the profession has been carried to an unprofitable extreme by the force of fashion in this matter. The lancet will be used again, not as a fashion, but as a matter of judgment, based upon knowledge."

—In a reprint before us, Drs. C. A. Oliver and C. H. Burnett, of this city, give the details of a rare and interesting case of recurrent dropsy of the left middle ear, complicated, after eight years' duration, by an acute attack of monocular optic neuritis (choked-disk) on the same side, followed by general tabetic symptoms; with remarks.

BOOK NOTICES.

A Manual of Obstetrics. By A. F. A. King, M. D. Second edition. Philadelphia: H. C. Lea's Son & Co. Small 8vo., pp. 338.

A condensed and yet not superficial presentation of the art of midwifery is satisfactorily accomplished by Dr. King in this little volume. He has not confined himself to what a student needs for his examination, and has omitted the discussions of debated points which take up so much space in the larger treatises. In the present edition he has increased the size of the book somewhat, and has carefully revised all the text. A sufficient number of illustrations are inserted to explain positions and instruments.

Female Hygiene and Female Diseases. By J. K. Shirk, M. D. 8vo. cloth, pp. 102. Lancaster Publishing Company, Lancaster, Pa.

It is a debated question how much information ought to be given to the public about diseases of females. We are and always have been in favor of teaching them freely, provided it is done in the proper spirit and manner. We can say of this little work that it fully meets these requirements. It is alike free from superficiality and sensationalism, and one should have no hesitation in recommending it to any woman who desired to acquaint herself with the hygiene of her sexual life. The author is a respected regular physician, and his volume is meritorious.

Legal Medicine. By Charles M. Tidy. Vol. iii. New York, Wm. Wood & Co.

This volume, one of Wood's Library of Standard Medical Authors, contains the portions on sexual crimes, asphyxia and suffocation. It is a very carefully studied treatise, though written from the English point of view, and not so useful to the American reader as one based on the practice of our own courts. The collation of cases is large, and they are presented in a thoroughly systematic manner.

The Medical Directory of Philadelphia for 1884. Edited by Samuel B. Hoppin, M. D., Philadelphia: P. Blakiston, Son & Co., 1884. 1 vol., 8vo. Price, \$1.50.

This convenient little volume contains a list of the Hospitals, Homes, Asylums, and Dispensaries of Philadelphia, druggists, physicians, medical societies, public boards, colleges, and the laws relating to practice. It will be found very convenient for reference, and as far as we have examined it, is quite accurate.

A System of Oral Surgery. Being a Treatise on the diseases and surgery of the mouth, jaws, face, teeth, and associate parts. By James E. Garretson, M. D. Illustrated with steel plates and numerous wood-cuts. Fourth edition, thoroughly revised, with important additions. 8vo. extra cloth, \$8.00. J. B. Lippincott & Co.

The treatise of Dr. Garretson has been markedly successful in the field which it occupies. Not only has it been found a standard work of reference for the surgeon and practitioner, but as a text-book for students it has been adopted by dental colleges throughout our country as the most approved system of oral surgery to be found. It is indeed remarkably complete, and one has but to turn over its leaves, or look through its index, to appreciate how exhaustively all the topics relating to this specialty have been treated.

If the investigation is pursued further, and an individual chapter is selected for perusal—as, for instance, the comprehensive one on "Associative Lesions of First Dentition"—the reader will find an excellent monograph, carefully condensed to the limits of a chapter, and expressed in language of admirable clearness.

Or again, take the last chapter, that on "Diagnosis," and we are presented with a most masterly exposition of this intricate subject, in which our judgment hesitates which to praise highest, the fullness of scientific knowledge, or the select phraseology in which it is set forth.

With regard to the present edition, it has been enlarged by several new chapters; much of the text has been rewritten and rearranged, and seventy-five new cuts have been added. The wide experience of the author in the field of his selection appears on every page.

The manufacture of the book is of the best character. In the somewhat over a thousand pages of text, there are more than six hundred cuts, and a number of steel engravings. While many of them are from other works, there are quite a number which are new.

We may say that this volume fills the demand for a book on this specialty, and while by revision and improvement it is maintained at its present excellence, there will not be room for another.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

THE DISCOVERY OF UREA IN THE SALIVA OF
PATIENTS SUFFERING FROM MORBUS
BRIGHTII.

That there are many varieties of morbus Brightii is a well-established fact, and that some varieties later will be proven to form a disease by themselves can scarcely be doubted. It is also well known that some forms of Bright's disease never evince symptoms of uræmia, that the patients suffering from one of these die of other complications, while there are again varieties of diffused kidney disease, in which the patient invariably succumbs to uræmia. The facts last mentioned have already found one explanation. In those forms of the malady where large serous effusions are a common occurrence, these watery accumulations have been found to contain great quantities of urea; the serous cavities are, therefore, in these cases *quasi* reservoirs for the surplus of urea, and the blood is kept comparatively free of this obnoxious and dangerous substance, while in those cases where dropsies and œdemas are rather rare, this great product of waste is bound to accumulate in the blood, if the latter has no other outlet for it. The kidneys are unable to excrete it in sufficient quantities, its excretion by the serous membranes is also at fault; the blood, therefore becomes the reservoir for it, and as a natural consequence we see that whenever the quantity of urea in the blood becomes sufficient to poison the latter, uræmia, *i. e.*, poisoning of the blood by accumulation of urea, takes place.

It was by no means foreign to the subject to suppose that in those cases of diffused kidney disease, where large watery effusions do not rid the blood of the urea, other fluids in the body would contain the urea, and this would be especially the case in that form of morbus Brightii, contracted cirrhotic kidney, in which, as is well known, serous effusions belong to the rare phenomena; yet, some cases, running their slow course for years, reach their fatal termination without almost the least œdema having made its appearance, while the sudden development of uræmia is as frequent as the fact that death usually assumes the latter form.

Dr. R. Fleischer has recently made this subject a special study. He supposed the saliva to contain urea in the cases which we last mentioned, and his laborious researches (published in the *Med. Chir. Rundschau* for 1883) proved that such does really happen. He discovered urea in all those cases where a cirrhotic kidney formed the malady, and in all others where uræmia appeared later or caused the death, even if at the time no symptom of uræmia occurred. His discovery, while it may lead to other interesting investigations, has probably also a diagnostic value. It is known that occasionally we meet with cases of contracted kidney, where for certain periods neither œdema or dropsy, nor albumen or tubercasts, are present, where the history alone, or the condition of the heart, the deterioration of the blood, or the examination of the retina, can instruct us regarding the nature of the case.

For this reason we will translate for the benefit of our readers the method employed by Fleischer.

To gain for the original experiments a larger quantity of saliva, one-third of a grain of pilocarpine was injected subcutaneously into the individual to be experimented upon. Thus larger quantities of saliva were procured than it had formerly been possible to obtain. For the first investigations he had 300 grammes (about $2\frac{1}{3}$ ounces) at his disposal; later, 800 grammes; then 2 litres; and finally 4 litres. The buccal cavity first was thoroughly cleaned, then the saliva immediately after its secretion combined with absolute alcohol, precipitated, then filtered, the filtered part evaporated, the residue treated with absolute alcohol, and after evaporation dissolved in amyl alcohol. By this method even very minute quantities of urea could be discovered. If the amyl alcohol is permitted to evaporate in a hot porcelain dish, any urea dissolved in it will separate itself in the shape of the finest needle-crystals, which before and after their change into nitrate of urea, may be identified either microscopically or by their chemical reactions. In healthy individuals (those first experimented upon) up to two litres no urea was discovered; in 3 litres (about 3 pints) such minimal

quantities were detected as to be unweighable. Such minimal quantities must be considered as irrelevant. But as this method permits the detection of $1\frac{1}{2}$ milligramme in 250 cbctm. saliva, it is more than sufficiently accurate.

In conclusion, we will add that Fleischer succeeded in every one of the cases mentioned above (cirrhotic kidney, and other forms of Bright's disease, where uræmia threatened), to demonstrate a weighable quantity of crystallized urea in 250 cbctm. saliva, and that the largest quantity he detected was 0.3 to 0.4 (about $\frac{5}{8}$ gramme) of urea per day.

THE PROPER METHOD OF MEDICAL LEGISLATION.

We often hear complaints by physicians that legislatures are so supine about passing laws regulating sanitary measures, creating health boards, against quackery, and the like. The fact is so: but what is the reason of it?

That it is solely to be charged to the general ignorance and neglect of public health in the minds of legislators, we do not believe. We should rather be inclined to put, if not the ignorance, at any rate the neglect, at the doors of medical men themselves.

They make no combined general effort to carry through a well-digested plan about which the large majority are in unison. If they did, there is little doubt they could carry any measure which they would thus unite upon. We have on various occasions put this prominently forward as the real cause of the failure to create a Board of Health for this State, and other similar legislation in any State; and we are reminded of it by a passage in an address on medical legislation by Dr. H. Hakes, of Wilkesbarre, Pa. His words present the subject so well that we extract them:

Preliminary to asking or recommending medical legislation, there ought to be something like unanimity and general agreement among the members of the profession as to the statute proposed to be enacted. As in any other matters of legislation, to be efficient the proposition requires united or concerted action and active work—in not exactly parliamentary, but common parlance, the legislature must be bored. We will do well

to simulate the methods of corporations, monopolies, temperance advocates, the liquor dealers, etc. As there will probably be no further meeting of the General Assembly within a year, let us improve the time, and through individual and societies' effort, inquire of each candidate for legislative honors how he will feel disposed toward those legislative measures which the profession are already agreed upon, and which are of urgent, immediate, and vital importance to the people of the State. An ordinary legislator is not such an awe-inspiring individual that we are to suppose he knows everything. Who among our number has spoken to our Representative in Congress about a more liberal appropriation for the National Board of Health? Probably not one; and yet if addressed by the two medical societies over which his constituency extends, I doubt not you would in due time hear a good report of him. And the same might be said of all the other members.

This, as the Romans used to say, touches the matter with the point of a needle—*rem acu tetigit*. It shows just where the trouble lies. The profession has not yet learned—though the lesson is not a modern one—that Wisdom may cry in the streets till she is hoarse and no man will regard her. She must do more than cry and preach. She must personally button-hole her hearer, and insist that he, individually, do what is required, until, at last, even if he be like the unjust judge, and respects neither God nor man, he will do it that she may cease troubling him.

Less metaphorically speaking, we must use our personal acquaintance with our legislators while at their own homes, to make them understand what we want, and impress it so often and so thoroughly on their minds that they will vote in favor of public health projects when they are brought up.

THE ECONOMICS OF DISEASE.

There is one side of preventive medicine that may be urged upon the public with a strong chance of securing their attention, and that is the expensiveness of disease. In their individual cases they appreciate it well enough, and often howl loudly about loss of time and heavy bills at the doctor's and druggist's. But with the narrow-

ness of view and selfishness of interest which generally characterize mankind, it is hard to get them to look at its cost in gross.

This may be estimated in several ways, and includes a number of factors. It has been calculated by statistical hygienists that of the cases of disease now current in civilized communities, about *one-third* could have been prevented by intelligent sanitation, personal or general. In our opinion this estimate is too low, rather than too high: but take it at one-third. Then the actual loss to these patients or their families is represented by one-third the whole amount paid doctors, druggists, nurses, etc., in a community, plus the loss of time, whatever that may be.

But this is only the first item in the bill of charges.

One-third of all the investment locked up in hospitals, dispensaries, asylums, homes, etc., could be placed to profitable and productive use were the laws of health observed.

Much more than this: numerous limited localities, vast tracts of fertile land, now shunned or but partly tilled, because of their ill report on the score of health, would be doubled, quadrupled in selling value and producing power, were they made free from the poisons which infest them. Millions of acres of the finest soil in the United States are lying idle by reason of the paludal poisons which are generated about them. Yet there is strong testimony that systematic action on the large scale can overcome these miasms.

We have spoken only of disease, but we must also take into account the sequelæ of disease in destroying ability to work, and thus casting the heavy expenses of permanent invalidism on the family or the commonwealth, or, by a fatal result, depriving the community of a life which would have possessed a value as capital applied to the production of wealth.

This has been the subject of calculation by political economists in England and Germany, and in both countries they have reached the conclusion that the value of an unskilled laborer, at twenty-five years of age, to his country, is \$1200. In other words, this is the average sum which

such a person will contribute during his life to the wealth of the community in which he lives. Now, if we suppose one-third the deaths in a community are preventable, we can readily see how much richer the community would be were it to exercise the necessary prophylaxis.

These are but a few of the practical considerations to which this subject leads, but they will serve as hints how strong a case may be made of this side of sanitation.

PHILADELPHIA SEWAGE.

That our sewage system, scanty and primitive as it is, is fundamentally faulty, the merest sanitary tyro knows full well.

Now that Boston has introduced a new and very good system of drainage, it will be in order for us to follow suit and to endeavor, if possible, to outdo our sister city. Our Public Buildings will, or at least *ought* to be soon finished, and then we presume that our rulers will be casting about them for some new job, and to save them trouble we will suggest one that will place our city, from a sanitary point of view, ahead of the world.

It has been calculated that the money value of the total annual excreta of each individual is two dollars. For our city this makes two million dollars that is annually wasted. This sum would certainly represent a very large interest on the cost that would be incurred in properly sewerage our city, and by a pneumatic system removing the waste to a distance and converting it into manure. Financially and hygienically, such a proposition should commend itself to our authorities.

NOTES AND COMMENTS.

Intermittent Fever Among Children.

A very valuable paper was that read before the British Medical Association by Dr. W. R. Thomas (*Brit. Med. Jour.*, January 19, 1884,) entitled "On Intermittent Fever Among Children in Low-lying Districts; Its Frequency and the Importance of Recognizing It, Owing to Its Curability." The symptoms he thus describes:

"The child for a few days appears to be cross and irritable, disinclined for fun or amusement,

and seems to be languid and excessively weak; the appetite is poor, and whenever moved the child cries, as if any movement gave rise to pain. After a time the patient seems to be cold; the face looks pale and pinched; the hands are shrunken and pale; the skin generally is dry and rough; the appetite is poor; the respiration is frequent, and the pulse is frequent and small.

"After a time, which is extremely irregular, ranging from half an hour to two or three hours, the skin begins to be hot and dry, the pulse, which before was frequent and small, becomes now full and yet frequent; the respirations become more frequent; there is want of appetite, great thirst, costive bowels, the urine is scanty and high, and occasionally there is slight delirium. This stage continues for from two to six hours.

"Then comes the sweating stage; the whole skin becomes bathed in perspiration, and all the symptoms abate; respiration becomes more natural; the pulse full, and less frequent; the appetite improves; the thirst goes; and a deep sleep comes on, from which the patient awakens apparently refreshed, but very languid.

"Such is a description of these cases when seen by the medical man daily; but generally speaking, in the out-patients' department in hospital practice, it is difficult or impossible to obtain a concise account of the case from the parent. This is the sort of a case we are apt to see. A patient, aged eighteen months, is said by the parent to have been becoming weaker day by day for the last two months. The lips and face are pale; the pulse frequent and weak; the appetite is poor; thirst is great; bowels costive; urine high; there is no lung or heart mischief; no abdominal signs of importance.

"In such a case it is often difficult to make a proper diagnosis; and when we see a patient daily becoming weaker, and more especially if we get a history of the heats and sweats, we are apt to look out for tuberculosis. I have many times been quite at a loss when trying to ascertain the cause. I have looked out for phthisis, pulmonary, or abdominal; and, thinking that the profuse perspirations, in the head and all over, the throwing off of the bed-clothes, the constant crying, as I presumed, from aches and pains, might be symptomatic of rickets, I have looked out for other corroborative symptoms, but have failed to meet with them.

"Whenever I meet with cases presenting such symptoms now, I always make particular inquiries as to where the patient is living, and

almost invariably find that the house is in a low-lying region of the town, that it has been, in fact, exposed to malaria, but not in the concentrated form which produces ague."

In these cases quinine acts like a charm.

Salicylic Acid In Cerebro-Spinal Meningitis.

The great fatality of this disease lends additional value to the article in the *St. Louis Courier of Med.*, February 1884, by Dr. D. C. Ramsey, which he thus concludes :

1. The analogy existing between rheumatism and cerebro-spinal meningitis would suggest and be good reason for the use of similar remedies in both diseases.

2. Salicylic acid being the best remedy, almost a specific in the treatment of acute articular rheumatism, would be a strong indication for its use in cerebro-spinal meningitis.

3. It produces a marked reduction in the temperature; the fever being thus lowered, the tissue-destruction and the onward progress of the inflammation is checked, thereby giving the patient rest.

4. It controls the intensely annoying metastatic pains of head, back, elbow, and knee, giving the patient ease.

5. It exerts a direct influence for good over the inflammation itself, and can be taken in frequent large doses without bad effect; having given a boy 15 years of age half-drachm doses every four hours for three or four days, with the only result of a great benefit in all the symptoms connected with the disease, is, I think, conclusive evidence of its harmlessness.

6. Its good effects are soon apparent, and it does not interfere with the use of other measures of relief, as ice, blisters, etc.

7. The best mode of using the remedy is to administer large doses frequently. For adults begin on doses of 15 grs. repeated every two hours, and increase the dose as may be found necessary to obtain the desired effect, to $\mathfrak{Hj}$, at intervals of two hours, if need be. When the disease is under control, which will be determined by the reduction in temperature, relief of pain, and placid countenance, decrease the dose, give at longer intervals, but still continue the use of it in small doses as long as the least symptom is present indicative of the disease.

Having never heard nor read of salicylic acid being used in the treatment of cerebro-spinal meningitis, and my good success with its use in this fearful epidemic being afterwards verified by Dr. J. B. Weaver, of this place, I hope to induce

others to give this remedy a trial, and by so doing I think they will be enabled to see very happy effects from its use, and thereby be highly gratified with the results.

The Tubercle Bacillus.

The question of the diagnostic value of this parasite has assumed such great importance that it behooves us to gather together all valuable opinions on the subject. Dr. G. H. Mackenzie has thrown additional light on the subject in an excellent article in the *Edinburgh Med. Jour.* for February, 1884, which concludes thus :

1. The bacillus of tubercle is pathognomonic of tubercular disease: found in the sputum, it indicates that active tubercular disease is in progress in the lungs, in the larynx, or in both.

2. It is absent in non-phthisical disease, in some cases of chronic (fibroid) phthisis, and during quiescent stages of the disease.

3. It is found in greatest numbers in acute phthisis with fever, softening, and cavity formation, but is also present in fair numbers before consolidation can be detected, especially if the larynx be affected, and it is thus useful in the diagnosis of incipient phthisis.

4. In a given case its numbers vary according to the nature and origin of the pulmonary secretion, and the period of the day at which it is expectorated, as also according to whether it is or is not free from extraneous matter in excess—*e. g.*, gastric secretion, saliva, or blood.

5. Found in the laryngeal secretion on its direct removal, it is a most valuable aid in the diagnosis of laryngeal tuberculosis.

6. In hemorrhage from the lungs, the presence or absence of tubercle bacilli in the hemorrhagic fluid has a most material influence on the prognosis.

7. Negative results in important or dubious cases cannot be held as conclusive unless examinations by different methods have been made on at least three different occasions.

8. Whilst its diagnostic value is thus of a very high standard, indicating the existence of tubercular disease, its prognostic value cannot be determined with accuracy, inasmuch as it may be as abundant in a comparatively slow non-febrile case as it is in a more acute and febrile one.

Pre-Fœtal Dilatation of Vulva to Save the Perineum.

Prof. Dunas, in the *Montpellier Médicale*, criticises the various methods of supporting the perineum, and comes to the conclusion that none of

them are either scientific or satisfactory. With Dr. Duke's method of stretching the perineum during the pains (*Brit. Med. Jour.*, 10th March, 1883), he expresses himself as not satisfied, and states that he believes such interference may occasionally lead to the occurrence of the accident it was designed to prevent. He draws attention to several cases of primiparæ noticed by him, where the vulva became quickly dilated, while the time taken for the head to reach the vulva had been long; and this he explains by the presence of a voluminous caput succedaneum in such cases, which leads to dilatation of the vulva while the head is still engaged dilating and passing through the vagina. The procedure he recommends, and which he designates "præ-fœtal dilatation of the vulva," consists in introducing two or more fingers and the thumb of the right hand into the vagina, and fitting the hand on to the head, not exerting any force on the approaching head, but rather allowing it to push the hand in front of it, and thus take the place of the caput in such cases as he describes.

Sudden Dislocations During Acute Rheumatism.

The *Dublin Jour. Med. Sci.* for December, 1883, says: In the course of a case of acute rheumatism, articulations in a bad position may suddenly become dislocated without bony alteration, and without suppuration. These luxations can be reduced instantaneously like traumatic dislocations, and the limb regains its natural appearance. M. Verneuil recently communicated to the *Société de Chirurgie* (*Gaz. Hebdom.*, 9 Nov., 1883), seven cases in which he observed this form of dislocation. At the present time such dislocations are attributed to hydrarthrosis. M. Verneuil does not deny that they may be due to hydrarthrosis, but he has never determined its existence. In two cases of luxation of the knee there was no fluid present. The muscular system plays a very important part in the production of luxations—paralysis existing in one group of muscles and contraction in another muscular group. It is important, therefore, to be on the watch for faulty positions of the joints in rheumatism. The reduction of these dislocations is easy, and subsequently the limb resumes its normal form and functions.

Common Salt in Pleuritic Effusions.

Dr. Tom Robinson, in the *British Medical Journal*, of December 22, 1883, relates a case of pleurisy with effusion, accompanied with "cold clamminess of hands and brow, and breathing 51 times

in a minute, the pulse barely appreciable at the wrist, and the heart pushed over to the right." He was ordered a teaspoonful of common salt dissolved in a wineglassful of water every hour, at the same time sweating by a hot wet flannel and a piece of waterproof sheeting. At the same time two ounces of the common black draught were administered, and all fluids were stopped. Two hours afterwards "he had most markedly improved in every way," his respiration being 48 per minute. In ten hours "he could lie on either side and get well down in bed." Next day there was no embarrassment of breathing, and all his subjective symptoms had disappeared. He was now given one drachm of common salt twice a day, with good nourishing food, and in a week he was up and out of doors.

Glycerine after Bathing.

Like the ancient Romans, D. S. Troy, of Montgomery, Ala. (*Popular Science News*), has taken to using glycerine after bathing, with most happy results. He puts one drop of attar of roses in two ounces of glycerine, and rubs the body after bathing. The result was charming: it left the skin soft, with all of its functions in as full operation as before the bathing, and with a delicious sensation of perfect cleanliness. He has been using it for four or five years regularly, leading a life more sedentary than ever, and it seems to supply to the skin a vigor similar to that resulting from muscular exercise. It has been of great benefit to his general health and personal comfort. No care is required in rubbing it on, except to see that it is applied to all the skin except the face, and particularly to the soles of the feet. If any remains after the rubbing, it can be readily wiped off with a towel.

Iodide of Potassium in Syphilis.

In the course of a lecture on the treatment of syphilis, published in the *Med. News*, Prof. Dujardin-Beaumetz says:

Whenever you give iodide of potassium in massive doses, do not forget that you must prescribe at the same time the milk diet. Milk, in favoring the elimination by the urine of the iodine, and in preventing the irritant action of this salt on the digestive tube, antagonizes the baneful effects of this medication. The solution which I advise you to use is the following:

R. Iodide of potassium, 225 grs.
Water, 8½ f℥.

M.
Each tablespoonful of this solution contains

about one gramme (fifteen grains) of iodide of potassium.

You should commence with small doses, and when the iodic coryza appears, discontinue for several days the use of the medicine, to resume it in larger doses. The economy in fact habituates itself to the iodide; and persons who, at the commencement of treatment, suffer from irritations of the mucous membranes as a result of small doses, a little later may bear without inconvenience much larger doses of this medicine.

Nitrite of Amyl in Pneumonia.

From *La France Méd.* we note that Prof. Silvestrini has been using nitrite of amyl in pneumonia, and he thus formulates his conclusions:

1. In the pre-organic stage of pneumonia, the nitrite of amyl may be of prompt and effective service.

2. One may repeat with impunity the inhalation of this remedy during several successive days, and in doses relatively enormous. (He has administered as much as 50 grammes of the nitrite in five days, the inhalation being carried on for five minutes every half hour.)

3. In cases which have a fatal issue, whether from extension of the pneumonia, or from complications, these inhalations may retard death.

To Hasten the Anæsthetic Action of the Ether Spray.

From the *Revue Méd.* we learn that a little device, first indicated by Dr. Letamendi, of Barcelona, is employed by Dr. Vidal to shorten the duration of the process of congelation. It consists in making a slight prick with a needle at the point upon which the spray is directed, at the moment when the skin assumes a purplish hue, and when the ether commencing to solidify assumes an oily consistency. The little puncture made at this time excites a reflex constrictive action of the vaso-motor nerves, the blood is driven from the part, and the skin becomes white. Another method of hastening the process consists in placing little wads of lint about the part, thus increasing the surface of evaporation.

Ether vs. Chloroform as an Anæsthetic.

Dr. J. W. Parkinson concludes an elaborate article on this subject in the *Pacific M. and S. Journal* as follows:

1. That ether is as efficient an anæsthetic as chloroform. 2. That there are fewer cases in which its use is contra-indicated. 3. That it is a

safer anæsthetic in the hands of the most experienced, and by inference corresponding in an increased ratio with those more or less unskilled. 4. That the use of chloroform with our present knowledge and experience, in preference to ether, where no contra-indication to the latter can be shown, is adding materially to the risk of the patient and the responsibility of the administrator.

A Ready Caustic.

From the *Jour. de Med. de Brux.* we learn that Dr. Moser recently presented to the Paris Academy of Medicine a little invention of his which he called the *crayon-feu*, for ready use in the application of the actual cautery to poisoned wounds from the bites of venomous snakes, mad dogs, etc. It consisted in a little cylinder with sharpened extremity, enclosed in a case which also contained matches for lighting it. The composition of the stick is as follows: Powdered charcoal, 30 grams; nitrate of potassium, 4 grams; iron powder, 5 grams; benzoin, 1 gram; agglutinating powder, q. s. To be made into forty crayons. These sticks are hard and burn readily, and for a sufficient time to cauterize the wound.

Death from Heart Rupture.

Mr. Baldwin relates a case in the *Brit. Med. Jour.*, January 5, 1884:

At the post-mortem examination, all organs were healthy. The pericardium was bulging, and, on section, was found to be filled with clots. The left ventricle was ruptured at the apex to the extent of nearly two inches; and above, to the extent of three-fourths of an inch. The aorta and valves were healthy; the mitral were slightly fringed with old vegetations. A huge clot filled the apical rupture, and in the heart, around the columnæ carneæ, some ante-mortem clots were found; the ventricular walls being thin at the seat of rupture. The patient had, eight months previously, lost a son from aneurism of the third part of the aorta; he had no other symptoms than persistent pain in the left mammary region, and in the neck.

A Tonic Pill.

The following formula is highly recommended in the *Med. Press and Circular*:

Reduced iron,	1 gr.
Ext. cinchona,	4 grs.
Arsenious acid,	$\frac{1}{10}$ gr.
Ext. nux vomica,	$\frac{1}{8}$ gr.
Gentian,	q. s.

For one pill. One three times a day.

Syrup of Coffee to Disguise Quinine.

Syrup of yerba santa has been satisfactorily used for this purpose, but now we note the following in *New Remedies*: Roasted coffee finely ground four ounces, alcohol one ounce, sugar twelve ounces, boiling water sufficient. Pack the coffee firmly in a percolator provided with a cover, and pour on boiling water until eight fluid ounces of percolate are obtained. Then dissolve the sugar (in the percolate) by percolation, and finally add the alcohol as a preservative. The taste of two grains of quinine is said to be pretty well covered by a drachm of syrup.

Phenic Acid in Yellow Fever.

Dr. de Lacaille, of Rio de Janeiro, professes to have cured thirty-eight consecutive cases of yellow fever by the use of Déclat's preparations of phenic and sulpho-phenic acids, and in grave cases, the phenate of ammonium. In the early stages he gives the remedies by the mouth, but in the advanced stages the hypodermic method is necessary. He contrasts very favorably his recent experience with his former sad failures without these drugs.

A Reliable Tœniafuge.

R.	Extracti filicis maris,	3 iss.
	Pulveris kamalæ,	3 ij.
	Mucilaginis acaciæ,	
	Syrupi simplicis,	aa 3 ij.
	Aquæ cinnamomi,	ad 3 ij.

M. S.—Half to be taken at bed time, and the other half early in the morning.

Mr. J. B. Lawson reports good results from this in the *Glasgow Med. Jour.*, January, 1884.

SPECIAL REPORT.

NO. XVI.—OPHTHALMOLOGY.

BY C. S. TURNBULL, M. D.,

Oculist to the German Hospital, Philadelphia.

Ophthalmia in the Expeditionary Force of Egypt. Med. Times, October 14, p. 447.

During the last campaign in Egypt 60 men per day became affected with ophthalmia. Oculists should accompany an army during such a campaign.

The Etiology of Hydrophthalmus. Centralb. f. Prakt. Augenheilk, August, 1882.

Mayerhausen saw hydrophthalmus develop during dentition under the symptoms of acute glaucoma. Eserine proved very efficient.

Parrot observed *Mydriasis during Coma* in fifteen cases of chronic infantile affections of the brain, as soon as he pinched the skin more severely. (Rev. de Méd de Paris, October, 1882.)

Minor. *Duboisine for Photophobia.* Virginia Med. Monthly, September, 1882.

Photophobia in keratitis disappeared very rapidly when duboisine was used, but not after atropine.

The Effect of Direct Sunlight upon the Retina. Arch. f. Ophth., vol. xxxiii., 3.

Deutschmann has found that direct sunlight produces changes in the retina similar to those of disseminated choroiditis. The retina is converted into a more or less structureless mass, the albumen being coagulated. Regeneration does not take place. The blood-vessels of the choroid in the region affected are widely distended, and small hemorrhages and little round nodules enclosed in spindle-cells are found.

Investigations on the Visual Perception of the New-born. Halle, 1882.

Genzmer thus describes the development of sight in the new-born: The eyes are sensitive to light immediately after birth, and the pupils react promptly. When a strong light suddenly falls upon them, they converge. A new-born child cannot follow an object with the eyes, but can fix upon it when in the line of vision. Perhaps this can be explained by an insufficient development of the optic tracts. The conclusion also follows that, at first, the child only has impressions of light and dark, which are mainly transmitted from the macula lutea. Convergence for the purpose of fixation was not observed until the fourth week. An energetic contraction of the ciliary muscle was observed with the ophthalmoscope in a child two weeks old, when convergence had been produced by strong light; this shows that there must be a pre-formed connection between convergence and accommodation. Colors are not noticed the first few months; white objects first attract the child's attention, no attention being paid to colored. The color sense begins to develop in the fourth month, red being recognized first, though white still takes precedence. It therefore follows that the new-born child is more affected by the quantity than the quality of light.

The Influence of the External and the Middle Ear on the Senses, especially Sight. Wiener Med. Blätter, No. 45.

Urbantschitsch has found that the perception of light is diminished by an affection of the ear; when the latter improves, vision also improves. He thinks it is a reflex action of the fifth nerve.

Aglave believes there are connecting fibres between the centres of hearing and color and perception. *De l'Audition des Couleurs*. Rec'd Ophth., No. 9, September, 1882.

The Good Results of Educating the Color Sense. Centralbl. f. Prakt. Augenheilk., December, 1882.

According to Kroll, 0.3 per cent. of the men in Crefeld and its surroundings, are red-green-blind, a fact which he explains by their occupation, silk weaving having been practiced for two hundred years, which had developed the color sense of the male population. By educating the color sense in the schools a similar result might be obtained for the population of the whole country. He therefore favors a plan looking to this in all the schools.

Myopia in the Trans-Caucasian Female Seminary, the Tiflis Military School, the "Zunker" School, and Artificial Illumination in the Classes and Dormitories. Medicinsky Sbornik d. Kaukas. Med. Ges., 1882, No. 34.

Reich's results were as follows: In the lowest class of the school for girls there was 12 per cent. of myopia; in the highest, 53 per cent., the average being 33 per cent. The development of myopia was due to the poor illumination in the lowest classes. In the three classes of the infantry school there are 52 myopes among 292 scholars. The ratio of the square surface of window to that of the floor was 1.12 and 1.16. The illumination at night was very poor. The majority of the myopes were Armenians.

Hysterical Ptosis. Ophth. Rev., December, 1882, p. 404.

Snell observed a case of hysterical ptosis in a girl about twelve years old, who had been menstruating for six months rather freely. She made a good recovery.

Stretching the Infra-Orbital Nerve for Chronic Cyclitis, etc. Ann. d'Ocul., 1882, vol. lxxxviii., p. 241.

Badal stretched the infra-orbital nerve, and excised a portion of it in three patients with good results. The affections thus treated were neuralgia of the trigeminus, chronic cyclitis combined with phthisis of the globe, and pains in chronic glaucoma (amaurosis). In the first case the infra-orbital nerve had previously been stretched with moderate success; in the second, peritomy had failed; and in the third, a broad iridectomy had proved of no avail.

Tearing the Supra-Orbital Nerve for Neuralgia. Soc. de Chir., Seance du 29 Nov., et 6 Dec., 1882. Gaz. d'Ophth., 1883, No. 1.

Blum hit upon this method by accident, as the

supra-orbital nerve tore while being stretched, the indication being neuralgia, lasting for fifteen years.

Traumatic Aneurism of the Orbit. Brit. Med. Jour., November, 1882, p. 1042.

Glascott observed a case of traumatic aneurism of the orbit producing exophthalmus. Patient derived great benefit from intermittent compression of the left carotid artery. The exophthalmus was reduced, and there was a cessation of whizzing in the head, and the infra-orbital bruit de soufflé disappeared. He also observed a case of aneurism of the orbit, which had existed for some time, which was cured spontaneously during an attack of phlegmonous inflammation of the face and head.

A Case of Intra-orbital Aneurism following Fracture of the Base of the Skull and Meningitis. The Lancet, November 11, 1882, No. 19, p. 799.

Lloyd observed a case of intra-orbital aneurism in a woman of twenty-nine, who had been thrown from a wagon, and had sustained a fracture of the base of the skull. Meningitis ensued, and in about six weeks the left eye began to become prominent and sight to fail. Ligation of the common carotid artery checked the growth of the aneurism for a time, but six months later, the eye being still prominent, it was removed on account of the pain; vision had been lost.

Contribuzione Allo Studio dei Tumori Vascolari dell'Orbita. Giorn. d. R. Acad. d' Med., d' Torino, 1882, Nos. 5 and 6.

Gallenga describes a curious case of unilateral exophthalmus observed at Raymond's clinic. The disease had begun with a marked swelling of the lids of the left eye about six years ago without any assignable cause. A year later, the globe, whose tension had increased a little, became slightly prominent, which gradually increased until finally it became at times a perfect hernia of the globe, the plane of the aperture of the lids falling behind the equator of the eye. The eye generally protrudes, and is turned downward and outward, but covered by the lid. Compression forces the globe back as upon a soft cushion; this is still more the case where the patient lies on his back and the carotid is compressed. When the pressure ceases, the globe springs back beyond, on the margin of the lid, and then gradually returns to its former position. The dislocation of the globe also easily takes place when the head is bent forward and the patient breathes out. Vision was gradually lost, and there is now atrophy of the optic nerve. The diagnosis of cavernous angioma was made on account of the slow devel-

opment, the absence of pulsation, the presence of a faint blowing sound, and especially on account of the power to replace the dislocated globe.

Further Investigations on Trachoma, and Remarks on the Origin of Blepharorrhœa of the New-born and its Treatment. Ber. über d. xiv., Versamml., d'Ophth. Gesellsch. zu Heidelberg, 1882, p. 45.

Sattler has repeated his already-published investigations on the development of trachoma through the agency of micrococci with special reference to Koch's method of breeding them. The culture and inoculation were completely successful, so that these results corroborate the former ones in every respect. As regards the morphology of the micro-organisms, they never assume the shape of chains or form large zoöglœa masses, but are either in small groups, single or double, though when fully developed the separate elements never come into immediate contact, but are always separated by a small interstice. One of the principal characteristics is the extensive subdivision of the trachoma nodule. The trachoma micrococci were bred through several generations. Sattler inoculated the human conjunctiva with micrococci of the third generation, which were purely bred. An eruption of trachoma granules followed, taking a mild chronic course. Only the micrococci of trachoma produce similar granules on the conjunctiva, while other micro-organisms introduced and rubbed into the conjunctival sac, produced no changes.

(To be Continued.)

CORRESPONDENCE.

A Word of Protest.

EDS. MED. AND SURG. REPORTER :—

Dr. Hiram Corson's article on "Blood-letting in the Young," published in your journal of February 2, contains one reckless expression, which seems to me to call for a word or two of protest. As Dr. C. is a physician of experience and standing, his utterances must command attention. Let him be most careful, therefore, to utter no word which may lead a hearer into difficulty.

He has seen fit to pooh-pooh some of the well-ascertained sources of danger that threaten us in our battle with disease. For instance, he does not see how a bubble of air carried along the jugular vein to the heart can cause death; indeed, he does not believe it can. As to how death is brought about in such a case, he is not more ignorant than the rest of us, but that the introduction of air into the organs of circulation may be followed by most alarming symptoms and even death, is a fact long known to our science. Mention is made of it in medical literature of earlier date than the middle of the last century. As an element of risk in surgical operations, Dupuytren

made it a subject of special study, and, since his day, a large number of cases have been put upon record, showing a most remarkable uniformity of symptoms and of post-mortem appearances.

Thirty-five years ago the symptoms of this accident were so well known that Mr. Syme told a jury of inquest that an autopsy was not necessary in order to prove that death had been due to the entrance of air into the anterior jugular vein, through a wound made by a seton needle (A mere puncture was made. The seton was not introduced.)

Death has followed the admission of air into the jugular vein, into the axillary, into the subclavian, into the sub-scapular, and into veins of so little anatomical importance as to be unnamed in the records. Effects more or less alarming have been observed to follow the entrance of air into the veins named above, and into the saphena and facial also.

From experiments on the lower animals, it has been learned that the presence of air in the portal circulation is attended with no untoward effects. In all other situations the effects are proportional to the quantity of air admitted and the rapidity of its introduction. Bretonneau caused death to ensue in half a minute by the forcible introduction of a very small amount of air, accidentally allowed to remain in the syringe with which he was about to inject some pus into the jugular of a dog. Not a drop of pus escaped from the syringe. Experience and experiment show that air may gain entrance into wounded veins which are not kept patulous by any anatomical or pathological condition. Cardiac diastole favors a condition of vacuum in the venous system, as does also the act of inspiration.

Enough has been said, I think, to show that this contingency, though somewhat remote, is quite near enough to merit consideration among the risks of venesection. A sufficient quantity of air to cause death may enter in so short a time, the effects follow with such appalling rapidity, and remedial measures are, so far as my knowledge goes, of such untried value, that it seems to me that no man without this forewarning should, at this day, be licensed to puncture veins. I am aware that this subject is scarcely ever alluded to in lecture courses, and quite as seldom in textbooks. This is a serious oversight. One would rather remain ignorant than learn this lesson from experience, whose teachings are so unforgettable and whose fees are so ruinous. Luckily, preventive measures are always effectual, at least in venesection. Still it is well to remember that he who is often surprised, may be sometimes demoralized.

JOHN S. FULTON, M. D.

Lakesville, Md., February 12, 1884.

—It appears that the suggestion of General Howard to "brand" deserters, which has excited so much indignation on the part of the public press, was totally misapprehended. The recommendation actually made was that after a first offense a distinctive mark should be tattooed (not branded) into the skin at some part covered with clothing, so that the offender should not be allowed to reënlist.

NEWS AND MISCELLANY.

The Bahama Islands for Consumptives.

A correspondent of the *Cinn. Lan. and Clin.* thus writes: The Bahamas are superior to any winter resort of the western hemisphere for pulmonary troubles. I presume they are not surpassed in the world, except by the Madeiras, and not even by them in the winter—only during other seasons of the year. Any consumptive, in its incipient stage, coming and remaining here for two or three full winters will assuredly get well. A patient in the second stage stands precisely an even chance of living or dying, while one in the third stage had better, of course, remain at home to die amongst his friends. The climate is equally as efficacious for nervous disorders, and very good for chronic Bright's Disease. It is not adapted to rheumatic affections but for other chronic maladies, chronic nerve disorders and albuminuria, it is, as before stated, unsurpassed. Of course, it is often difficult to induce patients to come here sufficiently early in the season, to remain here late enough in the spring, or to stay here at all. But that does not militate against the fact that the climate will do almost everything for them if they will be but contented to stay. I advise my patients to remain here till late in March or early April, and then not go home directly, where even at such late date there may still be experienced the rigors of winter. Rather, I recommend them to go to Florida or the Carolinas and work their way gradually northward, reaching the latitude of Cincinnati, perhaps, about the middle of May. The good that a patient has derived from a season here is often obliterated by a sudden transition from Nassau to New York, or some other city situated, perhaps, between 35° and 50° north latitude. In all the Bahamas the climate is, perhaps, equally favorable; but New Providence is usually chosen because it possesses the capital (Nassau) of the group, and because all the comforts of life may be readily and cheaply obtained here. The outlying islands possess so few comforts that an invalid requires, that he must be well enough to "rough it" somewhat ere he attempts to make them his residence.

Here (Nassau) we have the best hotel in all the West Indies, and also a number of excellent boarding houses, where every comfort may be obtained, in the latter at the rate of \$12 to \$15 per week, and at the hotel at about \$3 per day.

British Medical Association.

The fifty-second annual meeting will be held July 29, 30, and 31, and August 1, 1884, at Belfast, under the presidency of James Cuming, M. A., M. D., F. R. C. P. I., Professor of Medicine, Queen's College, Belfast. The Address in Medicine will be delivered by Sir Andrew Clark, Bart, M. D., F. R. C. P., Physician and Lecturer on Clinical Medicine, London Hospital. The address in Obstetric Medicine will be delivered by George H. Kidl, M. D., F. R. C. S. I., Master of the Coombe Lying-in Hospital, Dublin. The Address in Physiology will be delivered by Peter Redfern, M. D., F. R. C. S., Professor of Anatomy and Physiology, Queen's College, Belfast.

Communications in reference to the meeting of

the British Medical Association at Belfast, should be addressed to the Hon. Local Secretaries, John Moore, M. D.; Alexander Dempsey, M. D.; John W. Byers, M. A., M. D.

Visitors going from America to attend this meeting can travel by any of the following routes:

1. A "Cunard" steamer will leave (a) New York on Wednesday, July 16, arriving in Queenstown about the following Thursday week, July 24. (b) Boston on Saturday, July 19, reaching Queenstown the following Monday week, July 28.

2. A "White Star" steamer will leave New York on Saturday, July 12, and on Saturday, July 19; due at Queenstown about July 20 and July 27.

3. An "Inman" steamer will leave New York on Tuesday, July 15; due at Queenstown about July 23.

4. An "Allan" steamer will leave Quebec on Saturday, July 19, arriving in Londonderry about the 26th or 28th of July.

5. An "Anchor" steamer will leave New York on Saturday, July 19; due at Londonderry on July 29.

Londonderry is ninety-five miles from Belfast, and trains run daily between the two places.

The route from Queenstown to Belfast is from Queenstown to Cork, Cork to Dublin (one hundred and sixty-five miles by train), and Dublin to Belfast (one hundred and thirteen miles).

Carbonic Acid and the Devil.

In the *Popular Science News* we read that when Friedrich Hoffmann discovered carbonic acid gas, and traced its effects on animal life, he was denounced by more than one German university as hostile to religion, and verging toward atheism. Three or four students at the University of Jena, in the attempt to raise a spirit for the discovery of a supposed hidden treasure, were strangled or poisoned by the fumes of the charcoal they had been burning in a close garden-house of a vineyard near Jena, while employed in their magic fumigations and charms. Only one was restored to life, and, from his account of the noises and spectres in his ears and eyes as he was losing his senses, it was taken for granted that the bad spirit had destroyed them. Hoffmann admitted that it was a very bad spirit that had tempted them, the spirit of avarice and folly; and that a very noxious spirit—gas, or *geist*—was the immediate cause of their death. But he contended that this latter spirit was the spirit of charcoal, which would have produced the same effect had the young men been chanting psalms instead of incantations; and acquitted the devil of all direct concern in the business. The theological faculty took alarm; even physicians pretended to be horror-stricken at such audacity.

The Cholera Germ.

News from Berlin, dated February 19, states that the German Sanitary Commission which was sent out to Egypt by the Imperial Board of Health to study the nature and causes, etc., of cholera, and which, after finishing its labors at Alexandria, was ordered to continue its investigations in India, has just forwarded a report from Calcutta where it arrived some two or

three months ago. The Commission discovered the cholera germ in a water-tank at Calcutta, and found in the suburban village, where the cholera appeared, the same microscopic organism which had been discovered in the lower intestines of cholera victims in Egypt.

International Medical Congress.

The meetings of this Congress will begin at Copenhagen on August 10. A steamer will leave Hull (England) on August 2 and 9 for Copenhagen; and on August 5 a steamer will leave Leith (Scotland) for Copenhagen. Both these places (Hull and Leith) can be reached on any day by leaving Belfast on the previous evening by the cross-channel steamers. Visitors, after attending the meeting of the British Medical Association in Belfast, will have ample time to travel to Copenhagen for the Congress.

St. Louis Medical Society.

The following gentlemen have been elected officers of the St. Louis Medical Society for the year 1884:

President—G. F. Dudley, M. D.
Vice-President—Le Grand Atwood, M. D.
Treasurer—W. E. Fischel, M. D.
Recording Secretary—H. Hodgen, M. D.
Corresponding Secretary—G. Hurst, M. D.

First Advocate of the Germ Theory.

An esteemed correspondent claims that Prof. Rezin Thompson, of Nashville, was the first advocate of the germ theory in disease. Dr. Thompson died old, poor, and childless some twenty years ago; and if any of our Tennessee subscribers can supply us with particulars of his life and doctrines on this point, other than those contained in his published works, we shall be glad to receive them.

Statistics of a City.

Calling the population of Providence, R. I., 119,405 in 1883, the proportions of births, marriages and deaths to population in that year were as follows:

Births,	1 in 40.85, or 24.48 in each 1,000
Persons married, 1 in 50.76, or 19.69 in each 1,000	
Deaths,	1 in 51.29, or 19.50 in each 1,000

Philadelphia Dental College.

The twenty-first annual commencement of the Philadelphia Dental College took place at the Academy of Music on Friday, February 29. The address to the graduates was delivered by Prof. S. H. Guilford, and the valedictory by Edgar L. Gardiner. There were sixty-five graduates.

Items.

—The Philadelphia Clinical Society admits women to membership.

—Dr. H. H. Williams, of Johnstown, Pa., reports, in the *Medical Record*, a case of a man with three testicles.

—James H. Frey, wholesale druggist of Baltimore, Md., left in his will about \$60,000 to various religious and charitable institutions.

—Dr. Henry L. Sabin, for fifty-six years in practice at Williamstown, Mass., and the oldest trustee of Williams College, died in that town February 25, aged eighty-three years.

—On the occasion of the fourteenth annual dinner of Bowdoin College Alumni Association of New York, held at Delmonico's February 14th, Dr. Fordyce Barker was re-elected President.

—An amendment to the By-Laws of the Philadelphia County Medical Society has been introduced, and will be acted on in April, which provides that the members of the Society shall be regular male physicians.

—Dr. Lesnewich reports, in the *Paris Médical*, the case of a male infant, aged ten months, that secretes milk in considerable amount. The infant has, for its size, well developed mammary glands.

—One day Prince Bismarck, walking in a park, stood for a few minutes on an ant's nest. Hurrying home, he reported that he believed he had a bad case of trichinosis—he could feel the horrible things crawling through his system.

—"I have no objections," said a Chicago alderman, gravely, in speaking of the proposition to tax the druggists of the city \$500 per annum each; "I have no objections to druggists selling without a license on the subscription of a physician."

—Of vivisection Pasteur says: "Never should I have the courage to kill a bird for sport, but when it comes to experiments I have never been troubled by the slightest scruple. Science in that case has the right of pleading the sovereignty of the purpose."

—A new antiseptic termed "antibacterid," recently patented in Germany, consists of a solution of 338 parts of borax, and 198 parts glucose, in a minimum quantity of water. To this solution is added 124 parts of boracic acid, and the mixture is evaporated until solid.

—The Trustees of the College of Physicians and Surgeons, of New York, have elected Dr. John C. Dalton, for so many years Professor of Physiology, President of the College, in place of Dr. Alonzo Clark, who has resigned. Dr. John G. Curtis now holds the chair of Physiology.

—A *Lancet* correspondent quotes from the *Hygiène Pratique* that boots and shoes may be rendered water-proof by soaking them for some hours in thick soap-water. The compound penetrates the leather, and there forms a fatty acid which renders it impervious to water.

—It is said that Berlin has one drug store to every 16,266 inhabitants; Breslau, one to every 13,000, and Cologne, one to every 11,000. Compare these ratios with that of Chicago, where the proportion is one drug store to about every 1,500 inhabitants, and with St. Louis, Milwaukee, Detroit, Cincinnati, and other Western cities, where, we believe, the ratio is still larger.

—First Country Doctor: "Could you come to my place, Brown, to-morrow morning?"

Second C. D.: "All right, old man. What is it?"

First C. D.: "Well, I've had a case of endocarditis which I've very successfully treated with *convallaria majalis*, and I want your help with the post-mortem."—*Punch*.

LECTURE.

CLINICAL LECTURE ON DELIRIUM TREMENS.

BY B. BALL (PARIS).

Translated by Dr. A. A. Gleason.

(Continued from page 291.)

But if delirium tremens has its furies, there exists a much more violent form, in which agitation and foolish volubility take the place of the more dramatic incidents, the picture of which has just been traced.

During his incessant foolish recitals, the patient dreams of his habitual occupations; he believes himself in the saloon with his friends, or, perhaps, in the work-shop surrounded by workmen, he gives his orders, he directs imaginary work, he commands those about him, but without presenting, as in the preceding case, that excessive super-excitation, which resembles acute delirium.

There remains a characteristic which is found in all the forms of alcoholic delirium: it is the possibility of snatching the patient for a moment from his thoughts, and of obtaining from him a clear response to a definite question.

This waking lasts but an instant, but it has a capital importance for the diagnostician. It shows us, in fact, that, like the subject plunged into the *first delirium* of typhoid fever, the patient comes to reason for an instant when he is strongly solicited. A moment after, he falls again into his eternal monologue.

To these psychologic troubles, convulsive accidents are added; we remark the trembling first

of all—the importance of which is such, that, by good right, it occupies a place in the definition even of the disease.

The trembling may affect the hands, the superior and inferior members, the tongue, the lips, the muscles of the face; in short, in certain subjects the trembling is generalized. In applying the hand to the forearm, we feel the *subsultus tendinum*, which does not leave the patient a moment's rest.

Among the consequences of these motor disorders, we should note the embarrassment of speech, which may sometimes resemble general paralysis. Note, also, the unsteadiness of step and the impossibility of executing with the hands a slightly complicated motion, such as the act of drinking. All these phenomena are aggravated in an evident manner when the subject makes the least effort.

Among the general troubles which make a part of this procession of symptoms, one of the most striking is the profuse sweating, viscous and foetid, and often exhaling an alcoholic odor. As a compensatory phenomenon, the urine is scanty and red. Generally, there is constipation. The pupils are habitually contracted, but in certain cases they show a very marked inequality. In certain subjects a typhoid state remains, and sordes form on the tongue, the lips, and the teeth. The pulse is feeble, small, sometimes irregular, and often accelerated. According to Copeland, it may reach a hundred and twenty pulsations.

Amidst all these phenomena the temperature remains low enough; delirium tremens is an essentially apyretic affection, and if there exists a change in temperature, it is mostly in a sense of coldness, principally in the extremities.

There exists, however, a febrile form of delirium tremens to which Prof. Laseque, and more recently M. Magnan, have called attention.

In this form the temperature may be raised to 40° to 41° (Centigrade), and even in some exceptional cases to 43°.

This state is accompanied by dynamic phenomena, and the patient often sinks into coma.

According to foreign authors, the febrile forms of delirium tremens are in reality cases of acute delirium.

However, delirium tremens is recovered from in the majority of cases; its habitual duration is from three to eight days; in exceptional cases it may be prolonged to twenty, or even thirty days. The first phenomenon which announces healing, is the return of sleep.

There remains for us now to speak to you of the diagnosis and prognosis, the anatomical lesions of delirium tremens, and finally of the treatment which may suit it.

Diagnosis. In the presence of a typical case, offering at the same time psychological characteristics and the trembling which characterizes the disease, doubt does not seem admissible—above all, if the antecedents of the patient are known; and nevertheless there are cases where the signs of this disease may be the mark for an absolutely different visceral lesion. We cite principally pneumonia, typhoid fever, and acute meningitis.

Pneumonia, always serious in alcoholics, is one of the most frequent causes of delirium tremens; and what singularly augments the difficulty of diagnosis in such a case, is the absence of the complete signs of the disease. Neither the tenacious expectoration, nor the general prostration, nor the ordinary signs furnished by auscultation, are present to enlighten the physician, who besides cannot, by reason of exciting the patient, make a regular physical exploration.

The complexity of symptoms is then reduced to violent delirium, loquacity, accompanied by fever, sometimes by dyspnoea. However, we understand that by its action on the medulla, and by its elimination through the respiratory organs, alcohol may compromise hæmatosis, and even trammel the respiratory movements.

The diagnosis is often very difficult, even while taking into account the antecedents of the patient; and often it is the autopsy which comes, as a last resort, to adjudge the question.

As to typhoid fever, it is above all by the predominance of the abdominal symptoms that the physician recognizes the disease, which formerly, we know, gave rise to frequent deception.

Acute meningitis gives rise to accidents more clearly localized than those of delirium tremens. Contractions and paralytic affections are seen—occulo-pupillary disorders are present, intense headache, sometimes even vomiting—phenomena which are habitually foreign to acute delirium; it is the imperfect and insidious forms of meningitis whose undecided type leaves the observer in great embarrassment.

It may easily be confounded with delirium tremens. We do not seek to indicate the rules of diagnosis for each case in particular; let it suffice us to say that the antecedents of the patient, and the evolution of the disease, when it is carefully observed will in general allow us to recognize the truth.

There remains for us to speak of the affections which enter more specially into the scope of our studies.

General paralysis in its outset, encephaloid hypochondria, and above all, acute mania, may very often in their initial phases resemble delirium tremens. However, in a like case, we meet with less marked trembling with less profuse sweating, delirium less rich in hallucinations, a less absolute insomnia. All these characteristics are but relative; and we may say in general, that these affections are easily enough distinguishable from delirium tremens when their acuteness is moderated. In extremely grave cases all the elements of the drama are mingled, and it becomes almost impossible to separate the truth.

But, it is acute uræmic delirium which presents the closest analogies to delirium tremens—above all, when this latter is accompanied by fever. The symptoms may then present such a resemblance that it is only by reliance on the cause that the distinction may be established.

For the rest, acute delirium is an affection the outlines of which are not yet clearly enough traced to limit its domain with absolute precision.

Prognosis.—Delirium tremens has a grave prognosis. It is estimated that the issue is fatal in a proportion of 15 per 100.

Death comes usually during convulsions or coma. In the adynamic form the patient succumbs to a state of absolute prostration. Finally, certain patients die suddenly amidst the most violent agitation. (Marcé.)

Cure is the rule. It is announced, we have said, by the return of sleep, then by the successive amendment of the principal symptoms.

The agitation diminishes, the disorders of motility are effaced, the general delirium is calmed, and the patient returns gradually to the normal

state, sometimes after a short time, sometimes on the contrary after a prolonged delirium, whose traces remain for a sufficiently long time. There is a third mode of termination, which is met with frequently enough in subjects who present already a predisposition to insanity. Dementia and mental alienation may succeed, either directly or at a period more or less removed from an attack, and above all, after two or three attacks of delirium tremens. Let us add, finally, that relapses augment sensibly the gravity of the prognosis, and that the older the subjects are, the more chronic is their alcoholism, the more their general health is enfeebled, the more also do they find themselves exposed to the serious terminations that we have just indicated. On the contrary, a young man, vigorous and quite well, resists more easily the invasion of the disease, and may support more easily its consequences.

Pathological anatomy does not furnish in respect to this disease very scientific results, when we limit ourselves to the consideration of cases exempt from all complication.

A manifest congestion of the meninges and the cortical substance, a sufficiently characterized œdema of the pia mater, sometimes rudimentary adherences of this membrane with the cortical convolutions (as in acute delirium)—in short, a despoiled state of the membranes and a sufficiently marked lymphatic stasis—are almost the only lesions that may be attached with certitude to the disease with which we are now occupied.

The other alterations that have been proved—pachymeningitis, encephalitis, the presence of alcohol in the cerebral substance—are common to all forms of alcoholism, and present no particular significance.

Treatment.—The treatment of delirium tremens, about a half century ago, appeared to be admirably simple. Avoid sanguineous depletions, administer opium in large doses; such was the universal rule, and we can not deny the good effects of such treatment, in a great number of cases; but we know to-day that we must establish, in this respect, very narrow categories, and that it is impossible to apply the same medication indiscriminately to all diseases.

And first, when an alcoholic subject falls sick, the physician, if he knows the antecedents, should interdict all depressing treatment; no bleeding, no dieting, and above all no deprivation from alcohol; otherwise, we risk the provocation of an explosion of delirium. We should, on the contrary, tone up the patient and sustain him in as great measure as possible.

But finally, in spite of all precautions, the delirium breaks out; we may then find ourselves in the presence of three very different sorts of subjects.

Let us suppose ourselves called to a patient, young, free from all vascular or cardiac lesions, and showing no elevation of temperature. In such a case, opium is completely indicated; it must be administered in doses of several centigrammes, and we may also have advantageous recourse to subcutaneous injections of morphine.

We may join chloral to this treatment, especially if the agitation is great; finally, the patient must be sustained by the generous administration of wine and various alcoholic drinks. Chloroform and digitalis have both been employed. The first of these two remedies appears to us dangerous. As to the second, it is mainly when there is great feebleness, and an intermittent pulse, that it is indicated. We would never prescribe it in the enormous doses which have been employed in England (twenty-six grammes of the tincture of digitalis in ten hours). That, as we think, is a dangerous game.

Here, now, is a different—very different—case; the patient attacked by delirium tremens presents at the same time a visceral complication—a pneumonia, for example. In this case chloral is absolutely contra-indicated, opium should be administered with prudence; but we must, above all, insist upon tonics and diffusible stimulants, such as the acetate of ammonia; finally, have recourse to digitalis, if the character of the pulse indicates its use.

We must reserve a separate place for febrile delirium tremens, above all when it accompanies an adynamic state.

Narcotics are then formally contra-indicated; we must have recourse to tonics, to stimulants, to alcohol, and to anti-spasmodics, such as ether, camphor, and musk. Certain authors have recommended the acetate of zinc. Our personal experience furnishes us with no knowledge in regard to it.

COMMUNICATIONS.

THE OLEATES IN CUTANEOUS DISEASES.

BY HENRY W. STELWAGON, M. D.,

Instructor of Dermatology in the University of Pennsylvania, etc.

Attention was first directed to the existence of oleic acid about 1811, by Chevreul, and some mention of the oleates may be found in the pharmacy

of France of that time. The earliest English paper on the subject was by Attfield, in 1862.* It was not until the paper by Mr. John Marshall† was published, in 1872, that much interest was awakened in the subject. Since that time several communications on the oleates, both as regards their pharmacy and therapeutics, have appeared in the current medical literature.‡

The oleates must be looked upon as valuable additions to our means of treating diseases of the skin, and although they do not answer in all cases, or supplant the older and tried methods of dermic medication, yet they have proven of such value in a number of instances as to warrant their further trial and experimental use.

There are two methods of preparing the oleates, each of which has its advocates. The older method is by the direct combination of oleic acid with the base. The new method is by double decomposition, the oleate of sodium with a neutral metallic salt. Unquestionably the preparations by the latter method are, in appearance at least, superior to the older oleates; in regard to the therapeutical effects, they are also probably better, although excellent results may be secured with the preparations made by the older method. It is highly probable, however, that the method of manufacture by double decomposition will entirely supplant the old process.

Introductory to the consideration of the individual preparations, the following notes on the manufacture of oleic acid and the oleates may prove of interest:

First as to the preparation of oleic acid. One of the best and cheapest methods of preparing it is as follows: The oil of sweet almonds is saponified with the oxide of lead, having an excess of oxide of lead present so as to be sure of complete saponification of the oil. The product so obtained is put in benzine, which dissolves the lead oleate, while the lead palmitate is deposited. The solution of the lead oleate is decanted and shaken with diluted hydrochloric acid (1 to 7); this separates the lead chloride and leaves a benzine solution of oleic acid, which, after the expulsion of the benzine, gives an acid that is well adapted for the manufacture of the oleates. The oleic acid so obtained is of a light-yellow color, readily mis-

cible with 92 per cent. alcohol in all proportions without causing turbidity. (Wolff.)

The oleate of sodium may be obtained by saponifying the acid with caustic soda. A solution of this and a solution of a metallic salt brought together, will give a precipitate of the oleate.

As this method of obtaining the oleates by double decomposition is, however, somewhat expensive, the following method may be employed: One part of castile soap (sodium oleo-palmitate) is dissolved in eight parts of water; this is allowed to stand for twenty-four hours, when there will be a considerable deposit of sodium palmitate. The supernatant liquor containing mostly sodium oleate, is drawn off and decomposed with a concentrated solution of a metallic salt, which, if obtainable, should contain no free acid to prevent the formation of free oleo-palmitic acid. The heavy deposit of oleo-palmitate so derived is strained off, pressed out in the strainer, and the adherent water evaporated over a water-bath; afterwards it is dissolved in about six to eight times its quantity of petroleum benzine, and the insoluble palmitate is left to subside while the solution of the oleate decanted therefrom is filtered off. The benzine evaporated will yield an oleate that is a chemical combination, and one that will remain stable and efficacious. (Wolff.)

The oleates, whether made by the direct combination of the acid with the oxides or by the process of double decomposition, are fixed salts, and the designations of five per cent., ten per cent., etc., oleates, are misnomers, and wholly incorrect. The so-called per cent. oleates are solutions of the oleates in free oleic acid; for example, the so-called ten per cent. oleate of mercury is so named for the reason that ten parts of mercuric oxide are added to ninety parts of oleic acid, and combination allowed to take place. The oxide, however, only requires a certain proportion of the ninety parts of the oleic acid for the production of the oleate, so that there must be a considerable quantity of the acid which is not needed for the combination; in other words, the so-called ten per cent. mercuric oleate (and the same applies to the other per cent. oleates) is a solution of the oleate in free oleic acid.

It will be readily seen that this manner of speaking of the oleates, therefore, is not only misleading, but erroneous, and should be discarded. If a diluted oleate is required for application it may be ordered in the same manner that all dilutions are prescribed—so much of the oleate and so much of the diluent.

It is not my purpose to present in detail the

* *Pharmaceutical Journ. and Trans.*, 1862-3, vol. 4, p. 388.

† *Lancet*, May 25, 1872, p. 709.

‡ Crocker: *Medical Record*, 1879, p. 123; Wolff: *Amer. Jour. of Pharmacy*, Jan., 1879, p. 5; Nov., 1883, p. 445; Shoemaker: *Trans. Penna. State Med. Soc.*, 1879, p. 707; *Medical Bulletin*, July, 1882, p. 584; Squibb: *Ephemeris*, No. 6, Nov., 1882, p. 152.

chemistry and pharmacy of each particular oleate, as the foregoing remarks, with the subjoined table, showing the percentage of base in each salt, will give an insight into their mode of manufacture and composition :

For all syphilitic eruptions, ulcerative or non-ulcerative, and especially the later and localized manifestations, the local use of an ointment of this oleate is an excellent adjuvant to the constitutional treatment; it should be applied and

<i>Salt.</i>	<i>Base.</i>
Aluminium oleate contains 3.1	% metallic aluminium equivalent to 17.9 % aluminium hydrate.
Arsenic oleate “	8.16% metallic arsenic “ 21.5 % arsenious acid.
Bismuth oleate “	19.9 % metallic bismuth “ 44.3 % bismuthyl oxide.
Copper oleate “	10.1 % metallic copper “ 12.8 % cupric oxide.
Iron oleate “	9.04% metallic iron “ 11.5 % ferrous oxide.
Lead oleate “	26.7 % metallic lead “ 29.2 % plumbous oxide.
Mercury oleate “	26.2 % metallic mercury “ 28.35% mercuric oxide.
Quinia oleate “	57.2 % quinia.
Silver oleate “	27.6 % metallic silver “ 59.3 % silver oxide.
Zinc oleate “	10.4 % metallic zinc “ 12.9 % zinc oxide.

Oleate of Mercury.—In color, yellowish, somewhat adhesive, and of the consistence of ointment, with an oily odor. If pure, diaphanous and of a yellow color, but generally found of a grayish or greenish hue, showing the separation of mercurous oxide and metallic mercury, which will be found ordinarily at the bottom of the vessel containing it.

Applied to the sound skin, this oleate produces more or less redness and irritation, and if its use is continued, may cause a dermatitis. It is rarely prescribed in full strength, but usually one part to from one to three parts of oleic acid or lard. One part of this oleate to two parts of oleic acid will give a preparation about similar in strength to the so-called ten per cent. oleate. Of all the oleates, this is not only the most important, but one that has been long in use.

It has its principal field in the treatment of syphilis by inunction, and when employed for such purpose is efficient and cleanly, completely supplanting the old method of inunction by blue ointment. For this purpose, the oleate should be diluted with oleic acid, lard, or a combination of the two. A prescription made up as follows will answer admirably:

R. Hydrargyri oleatis,	3 iij.
Acidi oleici,	3 ij.
Cerati simplicis,	3 iij.
Pt. ugt.	

A portion of this ointment of the size of the terminal joint of the forefinger suffices for an inunction. For each application a new surface should be selected. As the oleate ointment is more irritating than the old mercurial ointment, and as it is, also, more readily absorbed, less friction should be employed, and the hairy and more delicate portions of the skin should, as far as possible, be avoided.

gently rubbed into each lesion. The ointment given above may be used; ordinarily, an ointment made up of one part of the oleate to four parts of benzoated lard will be found sufficiently active.

Another disease, in some cases of which this oleate seems to act almost as a specific, is chronic ringworm of the scalp. As a rule, it is, I think, more reliable than any other remedy, failing at times in obstinate cases, as do all other remedies, but in the majority of instances curing. In recent cases, a twenty per cent. ointment or solution will be effective; if the disease has existed a long time, a thirty, or even forty per cent. ointment may be employed. It is to be well rubbed in twice daily, and the head to go unwashed for a week or longer. Treatment, if it is to be permanently successful, must be continued for several months. Epilation, as in all other plans of treatment, is to be persistently practiced. A combination which will be found useful in these cases is the following:

R. Hydrargyri oleatis,
Picis liquidæ, āā ʒ ij.
Ugt. sulphuris, ʒ iv.
Ft. ugt.

It is to be applied morning and evening. As there is a tendency to chemical change, a quantity sufficient for a week or two only should be made at one time.

In all skin diseases in which ointments of red precipitate, white precipitate, and calomel are employed, this oleate, properly weakened, may often be substituted with advantage.

All indurations, swellings, and glandular enlargements, may occasionally be favorably influenced by applications of a mild solution or ointment.

In pediculosis capitis, and more especially in

pediculosis pubis, a twenty-five per cent. ointment of this oleate will often prove curative.

The mercury oleate, in some instances, may be advantageously combined with the other oleates.

Oleate of Zinc.—Dry, white, pulverulent, impalpable powder of a soapy touch, resembling powdered soapstone; if pure, should make a clear solution with oils, lard, etc., over a water-bath. It may be used either as a dusting powder or as an ointment. An ointment of one or two drachms to the ounce of cosmoline or any fatty base is most commonly used. Sometimes the oleate made up in ointment form with oleic acid seems to be more efficacious. A very good way of prescribing it is as follows :

R.	Zinci oleatis,	
	Acidi oleici,	āā 3j.
	Petrolati,	
	Cerati simplicis,	āā 5 iij.

Ft. ugt.

To a great extent this oleate replaces the oxide of zinc, and may be ordered whenever that substance is indicated. Acute vesicular eczema may be successfully treated with the application of black wash and the subsequent application of an ointment of oleate of zinc; the wash is to be applied with a sponge or soft rag for several minutes two or three times daily, after each application has dried, a small quantity of the ointment being gently rubbed over. In some instances, the disease seems to be more favorably influenced by the oleate employed as a dusting powder. When such is indicated, the following will prove an eligible formula:

R.	Pulv. zinci oleatis,	
	Talci veneti,	āā 3 iij.
	Amyli,	3 ij.

M.

This is to be dusted over the parts several times daily. The same plan of treatment is frequently of advantage in all weeping eczemas. In intertrigo, a dusting powder, such as given above, is very comforting. This oleate makes a harmless toilet powder, and combined with talc and calamine, as in the formula below, will make an excellent powder for such purpose :

R.	Calaminæ præparatæ,	3 ij.
	Talci veneti,	
	Zinci oleatis,	āā 3 vij.
	Olei rosæ,	q. s.

M. S.—Toilet powder.

This last may also be employed as a dusting powder in moist eczema and similar inflammations.

Oleate of Lead.—Yellowish-white in color, much resembling lead plaster, but somewhat harder and more brittle. A good ointment is made by melt-

ing with an equal part of oleic acid, vaseline, or lard; as such it makes an excellent substitute for Hebra's litharge ointment, and will keep for an indefinite time. It is protective, astringent, and sedative, and may be prescribed whenever such an ointment is called for. In acute and subacute eczema its use is followed at times by rapid improvement. In the more chronic and sluggish forms of the disease, a proportion of oleate of mercury may be added to advantage. In order to secure a rapid and positive effect, the ointment of lead oleate should be kept constantly applied as a plaster, changing twice daily. In abrasions, erysipelas, and similar inflammations, the oleate ointment exerts a prompt and beneficial effect, reducing the inflammation and relieving pain and irritation. In dermatitis venenata an ointment of the oleate, such as mentioned, allays the intense burning, and frequently affords relief. In that troublesome affection of eczema of the nares, where slight fissuring and pustulation take place, it will occasionally be found useful. In sycosis non-parasitica, the following formula will often prove of advantage :

R.	Zinci oleatis,	
	Bismuthi oleatis,	āā 3j.
	Plumbi oleatis,	3 ij.
	Adipis,	3 iv.

Ft. ugt.

This is to be applied to the parts twice daily, after thorough cleansing with warm water.

In eczema about the anus, this oleate ointment sometimes gives relief. Vesicular eczema of the hands may often be rapidly relieved in the following manner: The parts are to be soaked in hot water for ten minutes, carefully dried with a soft towel, and then are to be covered with pieces of muslin thickly spread with the ointment. The application is to be renewed morning and evening; at each renewal the loose scales, crusts, and epiderm are to be gently rubbed off; no force should be employed, otherwise more harm than good will result. Treatment is to be continued for several days, at the end of which time the hands will be vastly improved. So much accomplished, a small quantity of calomel may be added to the ointment, and instead of applying it in the form of a plaster as before, it should be gently rubbed in two or three times a day. It is well to remark that although the disease is quickly brought into a favorable condition by the plan of treatment just mapped out, the progress thereafter is not so rapid.

Oleate of Bismuth.—Pearly-gray in color, smooth, and of the consistence of ointment, and should show no trace of suspended solids when rubbed

these diseases, may corroborate the favorable impression already formed. The ointment which I have employed in the few cases referred to is the following:

R. Quiniaz oleatis,		3 ss.
Adipis benzoat.		
Petrolati,	āā	3 ss.
Ft. ugt.		

A small quantity of this ointment is to be rubbed in every evening, or less frequently, as may seem indicated.

In addition to the oleates already named, there are several others which have been employed in cutaneous diseases; but either they have failed to show any therapeutical effect, or experience in their use has been so limited as to make special mention of them at the present time unnecessary; these are the oleates of tin, antimony, nickel, cadmium, etc. The oleates of the alkaloids, morphia, aconitia, veratria, etc., are important, but as their use is confined to other than cutaneous medication, they fall beyond the scope of this paper.

Recapitulating, I may say that of all the oleates so far introduced for the treatment of diseases of the skin, the following may be considered as possessing therapeutic powers which experience has attested: Oleate of mercury, oleate of zinc, oleate of lead, and oleate of bismuth. The other oleates have as yet failed in adequately supporting any attested claim to curative powers; further experience in their use may, however, prove them worthy of a permanent place in dermic therapeutics.

In ordering the oleates, several points are to be kept in mind. If the action of the proposed ointment is to be mainly protective, then the oleate is best made up with one of the paraffinates; if there is to be a certain amount of penetrating power along with a protective influence, then a mixture of lard or oleic acid with a paraffinate is to be prescribed as the base of the oleate ointment; again, if absorption is the main point aimed at, then the oleate compound should be made up of lard, oleic acid, or a combination of the two.

In some cases (and they are by no means few) the oleates are found to disagree; instead of an improvement, a slight or marked aggravation occurs. In not a few instances this may be due to the bad quality of the oleate used; but that it may occur with oleates which are of the best manufacture, is beyond question. Oleates, if properly prepared, will keep almost indefinitely; but if prepared in the old way, with an excess of

oleic acid present, they will frequently be found to deteriorate.*

In conclusion, it may be said, as already stated in the first part of the paper, that the oleates are to be considered merely as additional means of treating cutaneous diseases, and are in no sense to be looked upon as panaceas, for often enough they must be discarded to give place to the older and tried methods of dermic medication.

APPARATUS FOR FRACTURE OF THE OS FEMORIS.

BY E. MICHENER, M. D.,

Of Toughkenamon, Chester county, Pa.

Since the publication of my paper on this fracture in the REPORTER, I have received so many applications for further information of my method, that I am willing not only to make that information more accessible, but now, after sixty years' experience in its use, to recommend it as superior to most of the methods usually practiced.

The idea was suggested, in part, by Amesbury's apparatus. The accompanying illustration is so plain as not to need much explanation of either its construction or application.

The major splint is made concave to receive the limb, then cut in two and united by hinges. These are held in position, at any desired angle, by the sliding brace and binding screw. The brass slide, secured by screw-bolts, serves to adapt it to the length of the thigh. At the foot a sliding standard is seen, carrying an adjustable laced shoe. Four brass buttons on each edge of the splint above the knee, and as many below, for the binding straps, and it is completed. These minor splints, from two to three inches wide, conveniently made by gluing narrow strips of light wood on muslin, and long enough to reach from the condyles to the top of the thigh; a bandage of strips made of strong muslin; padding for the splints; and eight pairs of straps of strong, unyielding leather, with buckles, complete the outfit.

After having carefully adjusted the fracture, and waited to see that no retraction takes place, remove the foot-gear, set the splint to the proper angle, and adjust the length of the thigh-piece by the well limb, so as to press against the ischium. Apply a few folds of soft flannel for a pad, and lay down the bandage of strips, or, as I prefer to do, apply the bandage when the fracture is reduced.

*L. Wolff & Co., Philadelphia; Theo. Metcalf & Co., Boston, and Parke, Davis & Co., Detroit, have furnished me with oleates well prepared and of good quality.

If found more convenient, the limb may be laid on the splint straight, and flexed afterward. The minor splints, either padded or rolled in flannel, are next applied, and the leather straps buckled firmly and as tight as the limb will bear. This completes the essential dressing.*

My purpose is to make a permanent, strong, steady, and even pressure on the entire tissue of the thigh, and the thigh only. It effects two important ends: 1. The muscles immediately lose their natural tendency to contract, avoiding both suffering and shortening; 2. It leaves both the hip and knee joint free to respond to any necessary or accidental movement of the patient. The reflex motion is received by the free joints, in place of the more fixed fracture-joint. My success, I believe, has depended upon these factors in the treatment. I have never used mechanical extension, more than what the angular splint may be supposed to afford.

The foot requires little—a stocking and support in or out of the shoe, and the avoidance of under-pressure on the heel.

*In irritable subjects, a bandage from the foot to the knee helps to quiet muscular disturbance.

For children, from infancy up, I have used extemporized splints made by cutting a shingle in two and nailing it on an angular block. This has always given satisfactory results.

The apparatus is equally adapted for injuries of the leg, and readily admits of lateral splints when required.

HOSPITAL REPORTS.

NEW YORK HOSPITAL.

CLINIC OF PROF. WILLIAM H. DRAPER.

Reported by W. H. SEELYE, A. M., M. D.

Constitutional Syphilis.

Patient was admitted November 12; is twenty-five years of age; unmarried. The family history is negative. Five years ago, after a suspicious connection, he says he had a large chancre on the right side of the dorsum of the penis, just beyond the glans. No symptoms of constitutional syphilis followed. Two years ago he had several additional sores on the penis, and the glands of the groin became enlarged; but these were painted over with iodine, and they soon subsided without breaking or suppurating. Three months ago he had a small sore at the meatus, and another about half an inch inside of the urethra. For this he was treated with injections of nitrate of silver, and with various patent remedies. The ulcer within the urethra was painful, but he does not know whether there was any induration about it or not. Two months ago he began to experience violent shooting pains in his joints, which radiated along his limbs. Six weeks ago a profuse pink macular eruption broke out on his chest, abdomen, back, buttocks, and extremities. There have been several similar crops since. He says there was also some eruption two years ago, but these sores were larger, and were elevated, and exuded a fluid which dried upon them and formed scabs. He has had one or two ulcers on the left leg and on the patella, the scars of which are still visible. On admission, his pulse was 75, respiration 18, and temperature 99.4°. There is at present an abundant, copper-colored, papular eruption extending over the face, trunk, and extremities; and on close inspection, numerous small pits or cicatrices are observable.

Gentlemen, in the clinical history of syphilis there are four stages, each marked by peculiar characteristics. There is first a period of incubation, during which there are no symptoms; second is the stage of primary lesions, or the period of the chancre; the next is the stage of secondary lesions, when the general eruption appears; and the fourth is the tertiary period, or the period of gummy growths, and visceral lesions. You noticed in taking this man's history that I was careful to locate accurately the time at which he had his last chancre. And I find that the general eruption, which he now has, appeared at just about the right length of time after the primary lesion, to show that it is a secondary manifestation of the disease. But the particular point of in-

terest in this case is the fact that the man thinks that he has had syphilis before. For he says that he had several sores, and a bubo two years ago. But it is not clear to me now that he has had syphilis before. The theory is, that a person who has had it once can not have it again, that he is protected from further attacks. I do not remember any case recorded of a second attack of syphilis. This man certainly had a sore on the penis, which was regarded as a chancre; but I must admit that I do not think that it was an infective chancre, for the man is now suffering from the secondary eruption of constitutional syphilis. You see, upon a close examination, that there are numerous small depressions on his skin. Now I am willing to assert with great positiveness that these are not the cicatrices of a former syphilitic eruption, but that they are the cicatrices of an acne which has been produced by the use of the iodide or the bromide of potassium. You know that there are certain drugs, which when given in small repeated doses, will produce in many persons a violent form of acne. And following this eruption you get just such cicatrices as these, which indicate that there has been a follicular eruption accompanied by a loss of tissue. We will probably find that this man was formerly treated with potassium iodide for his supposed syphilis, and these follicular cicatrices are the result. I infer, then, that it is pretty sure that this man never had constitutional syphilis, although he had had two chancres, until he contracted the chancre three months ago. So this is a very good case in favor of the theory of the dualists, that there is an infective and a non-infective virus. We can not say that this man was not susceptible to the syphilitic virus, for if this were so, he would have escaped infection from his last sore also. So we must conclude that his former chancres were of a different character from the one which appeared three months ago.

A noticeable and important feature of this last chancre was that it was located within the urethra, and was what is called a concealed urethral chancre. You will often find manifestations of constitutional syphilis in patients who cannot remember that they ever had any primary sore. They may be honest in their statements, but there are cases where the primary ulcer has been deeply seated within the urethra, and it may have caused a urethral discharge resembling that of gonorrhœa, for which they mistake it. And so they do not dream that they have constitutional syphilis until they get the secondary eruption, or perhaps not till they come to the period of gummy growths.

The history of this man's present disease is a classical history of syphilis. There is only one point lacking, and in relation to this he cannot inform us. It is the length of the period of incubation, from the time of the suspicious connection to the appearance of the local sore. This is often difficult to make out, because the patient is unable to individualize the occasion on which he became infected with the virus. But in a great many instances the occasions for exposure to this accident are so rare, that it is easy to determine the length of the period of incubation. The usual period is found to be between two and four weeks, or from eighteen to thirty days, the aver-

age being about three weeks. But the chancreid or non-infecting sore has no period of incubation. It may appear the next day, or two or three days after exposure. This is a capital distinction between a true syphilitic and a non-infective sore. Another distinction is that the infecting sore is generally single, while the non-infecting are often multiple. Both may be accompanied by an adenitis, but that due to the infecting sore is not attended by a suppuration of the glands; and it is a general adenitis involving especially the posterior cervical glands, and the chain of glands running down the arms, as well as those in the groins. And many other glands in numerous other places will be found to be enlarged and indurated. But the adenitis of the non-infecting chancreid is a single unique adenitis, due to a localized inflammation, which has extended to the chain of glands in the immediate vicinity of the sores. And here the inflammation is liable to go on to suppuration, which is the converse of what occurs in the generalized adenitis of the unique sore. In this man you can easily appreciate the generalization of the adenitis.

The generalized eruption of the secondary stage usually appears in from one to three months after the appearance of the chancre. And the period of its continuance varies very much. It may be six months, or one or two years. And often a much longer period will elapse before the appearance of the gummy growths characteristic of the tertiary period of syphilis. The characteristic eruption of the secondary period is of the erythematous variety, and it only involves the superficial vascular layer of the derma, and is thus analogous to the eruptions seen in scarlet fever, measles, and other exanthematous fevers. It may occur not only on the integument, but also on the mucous membranes, and it may be accompanied by a slight exudation from the papules, which are sometimes present. For we may get papules as well, and in all degrees. Or the eruption may be purely papular, or purely erythematous. Or it may be but scantily developed, or profusely generalized over the whole surface. As a rule the erythematous element is the more pronounced, however, while the exudation element is inconspicuous. This man has a very marked eruption on his face, which you might mistake for that which is found in German measles or in ordinary measles; and besides there is a little coryza, and irritation about the eyes, which are suffused, as is common in measles also. And when you come to look at the surface of the body generally, there too the eruption is suggestive of measles; for the spots almost disappear under pressure though not entirely, for a slight staining remains. There is also here a slight elevation of the eruption above the surface. But you observe that the eruption here is much more marked upon the back, and it has here a peculiar character which might excite your suspicions of its being of syphilitic origin. That is the fact that it is of a decidedly coppery color. You should not, however, lay too much stress upon the presence of an eruption with a coppery hue. And still another point, which will assist in diagnosing this eruption from that of measles, is the much greater length of time that this persists.

Sometimes the eruption does not occur upon the face and limbs, but it is confined to the an-

terior surface of the body. And in some patients it may be so insignificant as not to be noticed at all, and so they may not be cognizant of the fact that they have constitutional syphilis.

But it is not only the eruption and the adenitis which indicate the character of this man's disease, but it presents another interesting feature at this period of its development, and that is fever. Though his temperature on admission was only 99.4^o, and this morning it was normal, yet I will assume, and I am safe in assuming from the amount of the eruption present and the severity of the pain of which he complained, that he had already had considerable fever before coming here. In many of these cases of constitutional syphilis the period of the generalized eruption which follows the local manifestation of the disease, is ushered in or accompanied by a febrile movement of more or less severity. This is the period of so-called syphilitic fever, and thermometrical observations will generally show its presence. And it manifests itself not merely by elevated temperature and other objective signs, but also by the subjective phenomena of fever, such as headache, pallor of the skin, languor and drowsiness, rheumatoid stiffness, and pain in the bones, emaciation and so forth. These symptoms may extend over a period of several weeks. But sometimes the fever is very acute in its severity and course, and I have known cases with a temperature of 103.5^o where the pain was so severe as to require the administration of morphia for its relief. You will sometimes also get the distinct neuralgic affections in these cases, and the fifth cranial nerve is the one most apt to be affected. I have seen a neuralgia of the fifth nerve as acute as you will ever find under any circumstances. All the usual phenomena of this stage are presented by this patient.

I have already spoken once or twice of the analogy which is noticeable in the evolution of constitutional syphilis, to the evolution of certain fevers. And this analogy is so striking that it is worth bearing in mind. The evolution and duration of the different stages of syphilis, however, extend over a greater period of time. As in fevers, so here we have a period of incubation; and then a period of local manifestations, followed by a period of generalized eruption and constitutional symptoms, which lasts for an indefinite period; and lastly, a period of sequelæ, which is the period of tertiary eruptions and gummy growths. The analogy also holds in some other respects. For all persons are not susceptible to the syphilitic poison, which is also true of the contagious fevers. Many individuals are exposed to infection over and over again, but never take the disease, while others succumb upon the first exposure, and then they run through all the periods of the disease in a few months.

Now what is the prognosis in this man's case? Is it necessary that he should pass on into the tertiary period of the disease, sooner or later? This I can not say. He may pass into it, and he may not. The chances are that he will, but this is not certain. Many men go through the entire eruptive period, and then never suffer any more from the disease. But there are many more who do suffer afterwards. Nor can we say how soon the tertiary symptoms will appear after the disap-

pearance of the secondary. It may be in the course of twelve months, or in twelve years, or it may be never. It has been stated by some that a profuse generalized eruption is a more favorable sign than a sparse, or more papular one. But I do not think the truth of this fact has been well enough established as yet, to influence our prognosis.

Now comes the question, how shall we treat this man. In the treatment of constitutional syphilis mercury in some form is now commonly used. Both the mild chloride and the mild iodide have been much employed, as well as metallic mercury itself. Almost every practitioner has his favorite preparation, and mode of administering it. The protoiodide is ordinarily a very excellent preparation. If it produces digestive disturbances, diarrhœa, or colic, this trouble may be corrected by administering with a little opium. And, indeed, this combination is very common. The mercury is administered in the alterative form, in small repeated doses, with the idea of producing its specific effect on the gums. But it should not be carried so far as to ptyalize the patient profitlessly. However, you will often find great difficulty in ptyalizing a syphilitic patient. For syphilis seems to have a remarkable power of rendering the individual insusceptible to mercury, and so, much larger amounts are required to produce ptyalism than would be necessary ordinarily. The same is true as to the production of the specific effects of iodide of potassium, in tertiary syphilis.

There is another fact, gentlemen, which I wish to impress upon you, as it has so often been impressed upon me in connection with the toleration of drugs in disease. I refer to the fact of the intolerance of alcohol, which syphilis provokes in those who have it. I believe that it is now a well-established fact that a syphilitic patient can not use alcohol in any form without doing himself damage. And you cannot treat constitutional syphilis successfully if you allow the patient to use wine, beer, or spirits at all while he is under treatment. I cannot explain the irritating effect of alcohol on syphilitic patients, any more than I can explain why they can take mercury and iodide of potassium in almost unlimited quantities. The fact in regard to alcohol is however no more strange than that in regard to mercury and iodide of potassium.

This patient has been treated with the oleate of mercury by inunction. There are numerous methods employed for administering mercury. Such as by vapor, by inunction, by the stomach and by hypodermic injection. All these methods are used by different practitioners, and your choice will usually be made according to your own particular success with some one of them, or your affiliation with the views of some specialist. I have no particular form of administering to advocate. But if the patient can not take it by the mouth, you may give it by inunction. But this is not very practicable in private practice; for you must give special directions as to the place where it is to be rubbed in, and the amount, and the protection of the clothing from staining by the ointment, and so on. The oleate of mercury is a much neater application than the old mercurial ointment. The hypodermic injection is a very good way of producing ptyalism speedily.

Sometimes it may be necessary to give tonics in connection with the specific drugs. But as a rule mercury itself acts as a tonic, and improves the general system remarkably, and so precludes the necessity for iron or quinine or bitters. You will often see an emaciated and chlorosed syphilitic patient, improve at once upon the administration of mercury. You will find nothing more remarkable in the alterative action of drugs, than what is experienced in the treatment of syphilis by small doses of mercury. This is even more effective in improving the general quality of the blood than is iron under similar circumstances.

This patient will be under treatment and observation for a long time yet, and so you will be able to see from week to week the general improvement as it progresses.

MEDICAL SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

(Continued from page 302.)

Another curious thing, to be observed in the literature of hydrophobia, is the way in which the madness of the dog is often—one might say usually—deduced from the diagnosis of hydrophobia in the man; instead of the diagnosis of hydrophobia being made to rest upon reliable evidence that the dog was really mad, it is uncommon to find any proof whatever that a dog to which hydrophobia is attributed was rabid, this being, with rare exceptions, a pure assumption. The one phenomenon of a dread of water usually determines the conviction of the physician that he has a case of hydrophobia before him, and settles his opinion of any dog that may ever have bitten the patient, and cannot now be accounted for. Nay more, this mode of reasoning has led certain writers to the assertion that there may be a passing state in dogs in which they may communicate to a human being hydrophobia, but themselves recover. Thus is the struggle to support the specific theory kept up when circumstances seem to be most adverse to it.

Once more, and I am done for this occasion with objections to the anomalies which one meets in examining the basis upon which the general belief in regard to hydrophobia rests. I find in the recorded cases—with very rare exceptions—that, when once hydrophobia is suspected, every phenomenon that occurs during life, every lesion that is found post-mortem, is unhesitatingly set down as a feature of this disorder; and the idea does not seem to be entertained that many of them are grounds of suspicion that some other disorder is present. In this way all lines of distinction between hydrophobia and disorders which simulate it are erased; and it remains for every medical man who is called to a patient who has a dread of water, accompanied with exaltation of reflex excitability, to inquire for a bite or scratch of a dog or cat; if one cannot be drawn out, to assume that it has been received and forgotten; then to make a diagnosis of hydrophobia; after which it is only necessary for the patient to die, to make a complete record. If to this be added a careful

microscopical examination of the state of the brain and spinal cord, the observer will have an exact counterpart of the process by which the famous conclusions of certain investigators—often quoted by those who have not taken the pains to go to the evidence upon which they are founded—were arrived at.

This suggests a brief consideration of the pathological lesions of hydrophobia. Notwithstanding all the diligent endeavors made to learn something from the post-mortem examination of the bodies of dogs and men that have died of rabies or hydrophobia, one might to-day adopt the language of Dr. Hart, who declares (*Cooper's Surgical Dictionary*, art. "Hydrophobia") that these examinations afford "little else than a varied mass of symptoms, common to other nervous and blood disorders," and fail to "throw any clear light on the pathology of the disease."

I will not trouble you with the disappointed anticipations of the ancients in this connection: those of modern times are more instructive. The announcement by Hallier, in 1872, of the discovery of a micrococcus which was the germ of hydrophobia, and to which he gave the positive name of "lyssophyton," and the belief of Klebs in the parasitic nature of the granular elements found around the blood-vessels near the scar, have appeared and disappeared within the last decade. The hasty statement of Pasteur that he had obtained from the saliva of a patient dying of rabies a peculiar germ which, when he had cultivated it and inoculated the product, gave rise to a hitherto unknown disease, he was compelled to withdraw almost as soon as he had made it.*

The investigations of Benedikt, Coats, and Gowers, are of the greatest interest in connection with this part of our subject. They are often spoken of as if their results were identical and conclusive; although, in fact, they are neither. Dr. Benedikt published his investigations in 1875, in *Virchow's Archiv*. The text is accompanied with a plate which leaves little room for misunderstanding the author's meaning. The lesions described and figured consist of a perivascular exudation or extravasation (or both) of red blood-corpuscles, miliary spots of finely granular degeneration of the brain substance, "miliary abscesses," and melting down of effusions so as to make hyaline bodies alongside of the blood-vessels, often closing their lumen; while the vessels had a pigmented encasement (Pigmenthülle), made up of red blood-corpuscles. These lesions were found in both dogs and men. Dr. Coats published his discoveries in the *Medico-Chirurgical Transactions*, in 1878, accompanied also with plates. His investigations referred to tetanus and hydrophobia. He makes a point of the analogies between these two disorders; and, assuming a virus in hydrophobia, he argues backwards that there is a poison circulating in the blood in tetanus. The lesions he describes in hydrophobia

*Nothing daunted by the experience of others, I observe that Dr. Paul Gubler reported to the Acad. des Sciences, of Paris, on the 11th of June, 1883, that he had found a special organism in the rachidian fluid of animals that had died of rabies, and that the virus could be attenuated by means of cold. Another of the conclusions he announced at that time was that the disease is communicable from mother to fœtus.

consist of a perivascular infiltration with white blood-corpuscles.

In comparing these investigations, it is to be noted that the lesions Coats found in tetanus correspond much more closely with those Benedikt found in hydrophobia than do those the former found in his investigations of this latter disorder. Further, it is to be noted that he describes the perivascular infiltrate as consisting of *white* corpuscles, while Benedikt is clear in describing it as made up of *red* corpuscles. Finally, Coats does not consider (though most persons who refer to him speak as if he did) the lesions he found to be distinctive of hydrophobia, but simply evidence of irritation in the blood. Thus we see that these two investigators cannot be regarded as confirming each other.

Now the association of the name of Dr. Gowers (whose investigations are described and illustrated in the *Transactions of the Pathological Society of London*, vol. xxviii., 1877,) with those of Benedikt and Coats, as having found lesions pathognomonic of hydrophobia, is equally unwarranted, for he distinctly stated in answer to a question, at the meeting where he demonstrated his specimens (*Lancet*, June 9, 1877, p. 840), that his investigation did not lead him to believe there was any special lesion in hydrophobia.

But, inconclusive and conflicting as the results of all these careful investigations have been, it might be easy to see how they might be taken for more than they are worth, if it were not for the fact that they have been formally and categorically vitiated by the subsequent investigations of others. Thus Middleton (*Journal of Anatomy and Physiology*, 1881,) has published the results of microscopic examinations in which he found perivascular aggregations of round-cells in two cases of hydrophobia, corroborating some of the appearances described by Benedikt, but disagreeing with Coats and Kolesnikoff in essential points. But the most striking point of his publication lies in the fact that he found the same morbid appearances which were present in the cases of hydrophobia, in cases of purpura hemorrhagica, diabetes, fracture of the skull, erysipelas, head injury with hæmatoma, concussion of the brain with fracture of the spine, delirium tremens, peritonitis, tubercular meningitis, mental deficiency and excitement, hæmatoma, tetanus, and uræmia. His paper concludes with the distinct avowal that, "As regards the pathology of hydrophobia, it still remains true that nothing characteristic has been observed."

Another investigator, who has gone over this ground, and come to conclusions as destructive as those of Middleton, is Ivanoff, who says (*London Medical Record*, March 15, 1883, from *Vratch*, 1882, No. 15,) that similar appearances to those observed by Benedikt, Gowers, and others, are found in typhoid fever. One of the supposed characteristics, the transparent spaces, he says, were found by Popoff and Stephanoff in uræmia, and by Vinogradoff in intermittent fever, by Danillo in phosphorous poisoning, and by himself and Dr. Czorkov in the brains of healthy dogs. They have no pathological character whatever.

But I need not detain you with further references to more or less famous investigations. I will only add that they all tend to confirm the

opinion that as yet no gross or microscopical lesion has been discovered which can be regarded as pathognomonic of rabies or hydrophobia.

And now I must close. I have not said so much because it is any pleasanter or is likely to be any easier for me than for others to differ from the majority in the branch of science to which my life is given. It is with shrinking that I take a position which, if it is deemed worthy of notice, will be apt to excite opposition, perhaps condemnation. But I have now been engaged for nearly two years in a laborious study of the evidences upon which the general belief in regard to hydrophobia rests, and I have been gradually led to certain convictions different from those with which I started, and which I feel it my duty to make public. One of these is that hydrophobia is not a specific, inoculable disease, derived from the bite of a similarly affected animal. Another is that if we wish to have an accurate, scientific knowledge of what too often actually takes place, and is usually called hydrophobia, we must begin the study of it unprejudiced by the views heretofore generally entertained in regard to it, and with canons of criticism very different from those heretofore deemed sufficient.

I know that these convictions are not novel, and that they have been stated and defended with arguments before. I know, too, that they have heretofore failed to secure the assent of the greatest men who in every generation have adorned the profession of medicine. None the less, however, do I believe them to be true, and that the time will come when they will not be—as they have been in the past—characterized as too absurd to be discussed, or decried as too dangerous to be tolerated.

But, however that may be, a sense of duty compels me to join myself to the small minority whom I think to be on the right side of the question, for truth's sake. Further, in this matter, the interests of science are in an urgent sense the interests of humanity. For this reason one who feels strongly must speak boldly. This, then, is my apology to those who may think I have erred in opposing the opinion of so many men deservedly honored and respected in our profession.

[After the reading of the preceding paper:—]

Dr. Henry Hartshorne observed, that the author of the paper has given an interesting philosophical analysis of the confusion and uncertainty attaching to much of the evidence concerning hydrophobia.

But when the question occurs as to accepting the conclusion to which he has come, that no specific disease, resulting in man from the bite of the rabid dog, has been proved to exist, Dr. H. H. must necessarily dissent from this, for the best possible reason; namely, direct personal observation.

It had happened to him, early in his practice, to meet with a case, the history of which was known to him from the beginning. The essential facts were these: A boy, eight years of age, was bitten almost in front of the speaker's house, by a dog which, upon usual evidence, was considered to be mad. A day or two afterwards his father brought him to Dr. H. H., and, late as it was, excision of the bitten part was advised; this was, however, not consented to.

About a month afterwards, Dr. H. H. was called to see him. Not proposing to detain the College with all the particulars of the case, which was fully reported in the *American Journal of the Medical Sciences*, it may be said that it was studied without any prepossession or expectation as to what its course would be. Dr. H. H. had not, before that time, become very familiar with the clinical history of the disease. The most striking symptom, which may be considered, in the speaker's present judgment, to be pathognomonic of hydrophobia in man, was an *excessive reflex excitability of the muscles of respiration*. This persisted throughout the case. Not only an effort to drink a fluid, but the sound of running water, any sudden sound, a flash of light, even the puff of air made by moving the hand lightly above the patient's face—every such slight cause would induce a *gasps* of respiration, which gave rise to incessant distress, and made swallowing food or drink impossible. The boy was violently delirious; and this, as well as his age, and the peculiar character of his affection, put quite out of sight any suggestion that a *mental* cause, from horrible anticipation of hydrophobia (such as, no doubt, in several other cases has existed) could influence the case. He died in about a week from the beginning of the attack.

Dr. H. H. also afterwards saw another case; that of a man, under the care of the late Dr. Geo. W. Norris, in one of the surgical wards of the Pennsylvania Hospital. This patient was not delirious. In him also, the reflex inspiratory spasm was clearly marked; although, for a time, he could swallow moistened pellets of bread, or other solids, but no liquids. Along with this, it must be noticed, there was *in neither case* any *etanic muscular rigidity*. The absence of this at once differentiates such cases from tetanus; with which some authors, who have not *seen* instances of hydrophobia, have been inclined to conjecture their identity.

By such observations, confirmed by the records of many others in the literature of hydrophobia (which is not *all* confusion), Dr. H. H. has been obliged to conclude that there is a disease *sui generis*, to which that name, though not well chosen, may apply. Attacks do occur in men, after they have been bitten by dogs, which are unlike every other disease; therefore we infer the existence of a *specific* malady. It is, so far (with two or three *doubtful* exceptions only) invariably fatal. It may take place anywhere; even (as Dr. Dulles incidentally said) in Constantinople and Africa, notwithstanding the denial of this by some writers.

Against the horror and certain fatality of such a disease, granting its existence, the precautions now commonly taken are not at all excessive. It would be very unsafe for them to be relaxed, unless a clear case was made out of the actual non-existence of hydrophobia. It would be much to be regretted, therefore, that a conclusion, such as that of the paper just read, should go before the public, in the proceedings of the College, without protest; if, at all events, objection to it rested in other minds as well as in that of the speaker.

Dr. H. Hartshorne, after some further discussion, inquired of Dr. Dulles whether he rejected the opinion that *rabies canina* is inoculable from dog to dog?

Dr. R. P. Harris said: I have met with several cases of hydrophobia, and have been present when the disease was investigated by autopsy. I well remember the case of the boy just reported by Dr. Hartshorne. The youth and sex of the patient, the peculiar symptoms of his malady, and the history of his exposure to canine rabies, gave positive proof of the existence of hydrophobia. My father not having met with a typical case, in an extensive country practice of twenty years, was inclined to doubt the existence of true rabies, until I took him to see this case. Dr. Hartshorne was present, and we examined the patient critically, and with much interest. This was the first case my father had had an opportunity to see, although he had then been in active practice more than thirty years, and it had the effect of convincing him that he had been in error in regard to it. The existence of this disease in young subjects, of which there are many cases on record, clearly proves to my mind that it is a veritable blood-poisoning, and entirely distinct from hysteria and other neuroses. I have known a hysterical woman, under the fear of rabies, from having been bitten by a dog, manifest symptoms somewhat allied to those of hydrophobia; but a critical examination revealed the true nature of the disease. Such a case existed some years ago in Camden, and was very much talked about in Philadelphia; but the recovery of the lady satisfied the community of the true nature of the attack.

Dr. S. W. Gross asked Dr. Dulles if he desired to be understood as stating that hydrophobia was not a specific disease, but a pure psychosis.

Dr. S. D. Gross inquired whether Dr. Dulles was willing to be bitten by a dog suffering from hydrophobia as a test of his belief in the non-existence of the specific disease in man.

Dr. Dulles declined at present to give an answer to the inquiry of Dr. Henry Hartshorne; because to do so would involve a discussion almost as long as that of the paper he had read. He preferred at this time to confine himself to the subject of hydrophobia as reported to occur in man.

In reply to the question of Dr. S. W. Gross, Dr. Dulles said that if the specific element in hydrophobia be eliminated—as he believed it ought to be—there remained nothing except to consider the cases as pure psychoses, or as errors of diagnosis. It is, he said, remarkable how little physicians seem to be aware of the number of conditions in which, as is well known to students of the subject, the symptoms of hydrophobia are simulated. In reply to Dr. S. D. Gross, he said that the question the latter had asked proposed not so much a test of the truth of his convictions as of his personal courage, and this was not the subject under discussion. But he could say that there had been a disbeliever in the specific theory of hydrophobia who had been willing to show his faith by his works. In the beginning of this century, Dr. White, a young surgeon, of Brighton, England, had allowed himself to be bitten by a mad dog, and had inoculated himself with this dog's saliva, without suffering any evil effects in consequence.

THE ANNUAL REPORT OF THE LIBRARY COMMITTEE showed that there have been added to the library this year—

2186 volumes,
2107 pamphlets,
2862 numbers of journals.

The total number of volumes now in the library is 26,359. For the ensuing year, the Library will be kept open, except on Sundays and legal holidays, from ten o'clock a. m. to five p. m.

There are in the collection 3381 duplicates, and particular attention was called to this fact, inasmuch as it affords a rare opportunity to other libraries, of augmenting their list at comparatively small expense.

THE REPORT OF THE COMMITTEE ON THE DIRECTORY FOR NURSES

showed that the number of nurses registered December 1, 1882	209
Added during the year	104
Lost by striking from roll	6
Lost by withdrawal	4 10
Net gain	94
Present number	303

Total number of nurses furnished during the year, 733—an average per month of 61, as against 49 for last year.

Largest number (February)	84
Smallest number (August)	34

Sent outside of the city, but within the State, 63	
Sent to other States	59
Wet nurses furnished	17
Of registered nurses, there are males	39
“ “ “ females	264
Graduates of training schools	60
Non-graduates	243

The amount given to the library during the last year was \$200, and for the present year, \$300. Many physicians take great trouble and waste much valuable time in hunting up nurses personally; or, having obtained a good nurse through the Directory, they transfer her from one patient to another directly, instead of through the Directory. Were they to use the Directory they would obtain the same nurses, and add to the income of the Directory, and so to the appropriation to the Library.

It is the desire of the committee to make the Directory also a bureau for all needed information for the sick; and they have in contemplation measures by which, if any one desires to obtain boarding in the country, or at the seaside, for cases of whooping-cough, or for recent cases of measles, scarlet fever, or diphtheria; and for information concerning all appliances for the sick, such as invalid-chairs, wheel and other crutches, bed-rests, fracture-, water-, or air-beds, etc., he may obtain the object he seeks at the Directory.

EDITORIAL DEPARTMENT.

PERISCOPE.

Tobacco Poisoning.

The following valuable extract from a lecture on this subject by Mr. Jonathan Hutchinson, we take from the *Med. Times and Gaz.*, January 12, 1884:

In this connection let me relate to you a case which is instructive, although not so well authenticated as to detail as I could wish. I had the narrative from a medical man of great intelligence, who was himself the subject of it. He told me that some years before I saw him, he had for some months been “nearly blind.” He lost reading power, and “could scarcely recognize his friends.” He consulted, separately, four distinguished ophthalmic surgeons. One said that he could find nothing amiss, but gave a gloomy prognosis. Another thought the optic discs pale, and another, that all that he could see were unusually large physiological cups. Two conjured him not to smoke; a third said he might smoke as much as he liked; and another omitted any opinion on this point. He had been smoking very heavily, and drinking very moderately. The failure had begun whilst on a visit to Germany, when he had smoked still more than usual, but a mild tobacco. In spite of the advice given he did not, as he says, in any way diminish his smoking. He took strychnia until his muscles jumped, but was no better. On one occasion, whilst at his worst, he dined with a friend and took “quite as much champagne as a respectable person ought to do.” This was against

his usual habit, which was to be abstemious in wine. The result was that when he reached his home after the dinner, he found, to his delight, that he could read small print. In the morning, however, his sight was as bad as ever. At length he consulted a fifth specialist, who ordered him small doses of opium. Finding some, but not all the benefit he desired, he took not small doses but large ones, and had the good fortune to have his vision steadily improve, until he could see again almost perfectly. He had some difficulty in leaving off his opium, but gradually diminishing the dose, he at length did so. Now Dr. — assured me that he knew of no cause for this attack of amaurosis, nor of any explanation of its cure excepting that assigned. He had been in good health all the time, and neither before nor since had he suffered from any indications of nervous exhaustion. He was not overworked, nor subjected to any mental distress. You will see that I have no accurate information as to the degree to which the amblyopia had proceeded, nor excepting from what he remembered as to the exact state of his discs. Still, the case fits very closely indeed with the facts with which we have been familiar in a hundred instances of so-called tobacco amaurosis. I have seen many a patient affected in just the same way improve immediately and permanently on leaving off smoking. But here we are assured there has been no diminution whatever at any time. Let me say here that my patient was a man clearly fond of pictorial effect, and he may have unconsciously exaggerated. It

may have been that he did reduce his quantity or quality, it may have been that he indulged to very great excess before the outbreak, or that there was something in the German tobacco which he got which specially poisoned him. I incline, however, rather to the belief that we have here an instance of one drug efficiently counteracting the ill-influence of the other. The opium perhaps relaxed the set of blood-vessels which the tobacco had thrown into spasm. This suggestion is in keeping with what was noted after the champagne dinner.

I have known many cases in which the subjects of smoker's amblyopia recovered perfectly, although they never left off smoking; and of those who had given it up for a time, I do not know that I ever once witnessed a relapse when the habit was, as it always is, resumed. It may be thought that such facts go against the belief that tobacco has anything to do with it, and that this is made almost a certainty by such a case as that which I have just related. For myself, I do not think so. Show me parallel cases occurring in those who do not smoke. It is possible that even one or two of such might be produced, but they are infinitely rare; whilst in heavy smokers, this form of transitory amaurosis is an everyday occurrence. If cases were forthcoming in which there had been no smoking, my reasoning would be this—there is probably a form of nerve disorder, perhaps a passing neuritis, perhaps only a vascular ischæmia, which may be induced by exciting causes of the precise nature of which we know nothing, but concerning which it is still in the highest degree probable that something acts as the predisposing cause. No doubt there is idiosyncrasy in the furthest background; as a middle stage, the long-continued habit of smoking; and lastly, some unrecognized influence—some depression of nervous tissue perhaps—which determines the attack. The final exciting cause may in some cases be important, and in many it may perhaps be absent, the tobacco being itself sufficient.

You will see that these conjectures open to us a very interesting chapter in reference to the influence of drugs in general, especially of those drugs which we give over long periods of time, and of those which become, with many persons, articles of ordinary use quite independent of medical prescription. We do not know but what other articles of which the chief influence is upon the nervous system may after long continuance produce injurious results. We can by no means safely assume that because a nervine stimulant is borne with impunity, or even with apparent advantage, that therefore it is wholly innocuous. It may be that its use involves the risk of very peculiar and wholly unexpected disorders. In the light of this conjecture we ought to examine as to all that is possible in reference to the different kinds of wine, tea, coffee, hops, quinine, absinthe, chamomile, and many others. I shall ask you presently to observe the facts as to the connection between arsenic and attacks of herpes zoster, facts which are, let me say, somewhat similar to those in reference to tobacco and attacks of amblyopia. Before proceeding to this subject, I wish to take an illustration from an article which comes into the diet category. The study of drugs is often

sufficiently difficult, but that of diet is surrounded by peculiar fallacies. Especially we must remember that both in prescribing and in feeding, combination is often everything. A thing which might have agreed well alone, may poison when taken with something else; or conversely, that which alone would certainly have disagreed, may go all right with its proper adjunct. If you put tannin with your tobacco, a man wholly unaccustomed to smoking may take a pipe with impunity. So, also, camphor counteracts the effect of tobacco, and belladonna prevents the headache from opium. Not only must we keep in mind, in all questions of diet, the possible influence of some unremembered combination; but we must bear in mind, that the state of the individual varies at different times. Most of our patients are marvellously unobservant in these matters, or, rather, observe in a hurry, miss out facts, and arrive often very confidently at most erroneous impressions. Sometimes, however, we chance upon an acute and careful witness as to his own health and the things which help or hurt him. When such is found, prize him and listen in patience to his narrative. I have told you in a former lecture how in respect to "egg poisoning" it is often unsuspected by the patient, and how, also, in some cases it is only in certain conditions of health and under certain circumstances that eggs do disagree. Now, just the same is true of tea and coffee; they will agree under certain conditions, and not under others. The man to whom tea has appeared for years to be an essential of comfortable existence, may suddenly find himself compelled to abstain from it. It may be that slowly this beverage has itself induced a change in the state of the nervous system; but it may also be that some other change in diet has taken place, or, perhaps, that it is the mere result of advance in age.

A Case of Retention of a Mummified Three Months' Fetus until the Seventh Month after Conception.

Dr. I. Henry Fruitnight reports this case in the *Am. Jour. Obstetrics*, January, 1884:

In the latter part of April, 1883, Mrs. S. menstruated for the last time. Soon afterwards she developed the usual sympathetic and reflex symptoms of pregnancy, such as "morning sickness," shooting pains in the breast, languor, etc., and at the same time noticed that her abdomen, as well as her breasts, were increasing in size. As she had already borne three children, she naturally concluded that she had become pregnant for the fourth time. I had attended her during the last two confinements, both of which had been normal in every particular. In the middle of August she was very much frightened by the occurrence of a convulsion in her youngest child. A few days subsequently, on August 17, she observed a discharge of blood from the vagina, but unaccompanied by pain. The bleeding, which was not profuse, continued for a few days, and recurred later in the month. On September 5 it again appeared, and she presented herself before me for examination. On physical examination, I found a little oozing from a very slightly patulous os. The uterus was enlarged, but it seemed to me not quite so large as it should have been at the supposed period of pregnancy, now about four and

one-half months. My diagnosis was a partial separation of the placenta from the uterine wall, and hemorrhage as a result, both into the placenta and externally. I advised quiet and rest, and prescribed grt. x. ol. erigeron canad. on sugar every two hours, until hemorrhage ceased. I did not see the patient again until November 3, when she continued the history as follows: She said "that she almost doubted that she was in the family way, because she was now near her seventh month, and had never felt life, though she thought that at one time she had been aware of the movements of the fœtus. Moreover, after the last discharge of blood, she said that she had grown smaller around the abdomen, and that her breasts also had become smaller; and she also stated that at about the time of the first bleeding, the reflex symptoms of pregnancy, as vomiting, etc., had disappeared."

I appointed a day for a physical examination, but on the following day, November 4, I was hastily summoned to my patient's home. She was suffering from uterine contractions, and was bleeding from the uterus. I made a digital examination, and discovered a globular body, about the size of a hen's egg, protruding from the os uteri, and by my manipulation it was ruptured, and a fluid escaped. Nothing further could be detected, but when I withdrew my finger, I observed a piece of membrane adhering thereto. She was placed upon ergot, fluid ext. Squibb, ʒj. every two hours.

I again examined her on the following day, and detected what I surmised to be the leg of a fetus of about the third month of development. But as it could not be budged, I decided not to interfere, but continue the ergot as before. On the evening of the same day I again visited my patient, and was then enabled to deliver her of a fetus. My surmise had been correct; it was a foot presentation of a fetus of the development of about three and one-half months. Its form, however, was flattened from compression. It was very friable. The viscera of both the thoracic and abdominal cavities were exposed to view, and very small and shrivelled. Its color was of a dark brown, and it was leathery and wrinkled, and hence called a mummified fetus. And as Prof. Lusk says, on p. 288 of his admirable treatise: "The subcutaneous areolar tissue had disappeared, and the skin lay in direct contact with the muscles." No trace of putrefaction was discoverable. The umbilical cord seemed normal, though somewhat long. After the fetus had been removed, I attempted to reach the placenta, but I was unable to do so. I continued the ergot as before during the night, hoping that it might be expelled naturally, as it eventually was at some hour in the night.

The placenta was quite small, measuring $3\frac{1}{2}$ inches longitudinally, and $2\frac{3}{4}$ inches transversely, and having an average thickness of $\frac{7}{8}$ of an inch. It weighed about $2\frac{3}{4}$ ounces. Its tissue was very hard, dry, tough, and yellowish. It showed traces of fatty and fibroid degenerations.

On one edge of the circumference of the placenta were the remains of a large decolorized clot, evidence of an earlier hemorrhage, possibly of the one in August. There were also to be seen recently formed clots.

It seems to me that this is a quite uncommon and interesting case. Most probably the first hemorrhage caused the death of the fœtus, and induced the changes in the placenta. The integrity of the membranes preventing the access of air, explains the immunity from putrefaction. This arrest of development and mummification of the fœtus, and its subsequent retention in utero for many weeks and months, and at times even beyond full term, happens more frequently in twin or multiple pregnancy. In these last cases, quite often one of the fœtuses becomes a victim to this perversion of nutrition; one fetus maturing normally, the other mummifying. But in a single pregnancy, as the case just related, it occurs very infrequently. From the whole clinical history of the case, the fœtus must have been blighted at about the third month, and remained innocuous in utero for four months, before nature took it upon herself to expel the intruder from the uterus. Neither parent exhibits any syphilitic taint, nor have they ever suffered from specific constitutional infection.

The Unity of Poison in Diseases.

Dr. G. De Gorrequer Griffith read the following paper before the British Medical Association at its last meeting:

In the year 1875, I first called attention to the fact that what is termed scarlatina occurring in the puerperal is frequently not scarlatina at all. But, before I proceed further, I must explain what I mean. I hold that there are two forms of scarlatina; the orthodox—viz., that contracted from a previously affected person, or something infected thereby—and the septicæmic, or toxæmic—viz., that which is evolved or generated *de novo*, as a result of autogenetic blood-poisoning, such as occurs in puerperal cases, or is evolved as a consequence of hetero-genetic blood-poisoning, such as arises (where no scarlatina had existed before) from drains, sewers, imbibition or ingestion of deleterious articles of drink—water, milk, cream, etc.—or of food; and from decomposing animal or vegetable substances. This toxæmic or septicæmic scarlatina, which is evolved from the above causes, is identical with the "surgical scarlatina" of Paget; and will, on strict investigation, be found to be the form of scarlatina which more usually prevails among puerperals. In saying, "It is not scarlatina at all," I mean it is not the orthodox—namely, that which is recognized by all the profession, and is, as all agree, contracted from a previously-infected person or thing.

While carrying on this investigation, I was struck with the unity of origin in cases of puerperal fever, and typhoid also; and, in pursuing the inquiry, found how, from the same source, there would spring erysipelas, scarlatina, typhoid, puerperal, and diphtheria fevers; sore umbilicus in infants, sore eyes, sore mouth, and sore throats, embracing a very wide area of inflammation and inflammatory conditions of palate, tonsils, pharynx; and, passing still further on in the respiratory tract, the larynx, the bronchi, the pleuræ, or the pleuræ and lung, would be found involved; so that toxæmic or septicæmic laryngitis, bronchitis, pleurisy, pneumonia, and pleuro-

pneumonia, attacking a variety of persons, may all, as in the case of the other forenamed ailments, viz., toxæmic, typhoid, etc.—as I call them, to distinguish them from the orthodox—be traced to the same causes; as could also hepatitis, diarrhœa, dysentery, cholera, enteritis, hemorrhoids, and a large number of affections hitherto considered to be utterly distinct, and having no connection with each other, no point in common, no place where all meet together, because they diverge so much afterwards. Hence, I formulated, as a heading to my papers, unity (as regards origin) of poison in the diseases I have just enumerated, and in many others, usually considered to be separate and entirely distinct.

This unity and differentiation in the course of evolution is now recognized by many medical men. Moreover, I found one disease (I adhere to the current word), or, as I term it, one set of symptoms, to be evolved from another, in some cases so far apart in nosological arrangement as to be said to be wholly and entirely distinct, distinct even to specificity; and a number of nosologically divided diseases (sets of symptoms) to be evolved from the one unity-point, the one common ancestry—differentiated no matter how widely, as they actually become, afterwards. I have, therefore, extended the formulated heading into "Unity of poison in diseases usually considered to be separate and entirely distinct; and the evolution of one from another apparently quite distinct, and of many diseases—seemingly all different—from one unity or common origin;" evolution from this unity leading to differentiations. Further, I recognize that symptoms occurring in the course of an affection, say such as scarlatina, symptoms which ordinarily are termed "complications," may become primary motors of disease, originating a fresh epidemic, it may be—fresh, inasmuch as it would differ from that in the course of which it was itself evolved. For example: Diphtheria not unfrequently is met with as a "complication" of scarlatina (I would say it was part and parcel of the scarlatina), which, in this instance, would be spoken of as the primary disease, the other as being secondary; this latter would be conveyed to a number of persons, even to such a number, it may be, as to constitute an epidemic, spreading fast from one to another. Then this diphtheria would cease to propagate itself, or would cause something quite different to be evolved, or would cause diphtheria to be evolved in the persons exposed, or in the course of these evolutions it would hark back to that which set it agoing—viz., scarlatina; or there would originate or evolve, in a number of the exposed, certain other symptoms, usually considered sequelæ, but not actually part of the scarlatina; so that another outburst of something, seemingly altogether different from scarlatina and diphtheria, would take place, to cause perhaps another new evolution; or, again, to hark back to scarlatina or diphtheria, or both combined, as it would be termed; or would, as it were, leap forward and cause to be evolved, in a certain number of cases, a very ulterior sequela of scarlatina—say rheumatism, or rheumatic fever, and heart and pericardic affections; or the latter *per se*; or, it may be, nephritis (the scarlatinal form) would be evolved, without any other intermediate symptoms being noticed, or any pre-exist-

ing warnings having been detected, or indeed been noticeable or detectable, such a form of nephritis as would be infectious—infective nephritis, I would call it—inasmuch as it has the power to set up scarlatina, or diphtheria, or any other ailment or group of symptoms coming within the range of its infectivity. In this way, new sets of symptoms may be evolved, new outward manifestations of the inward workings or evolution, a new disease in fact, as would be said in current medical phraseology. In this I am fortified by the Bradshawe Lecture of Sir James Paget, and his and Sir William Gull's addresses on "Collective Investigation of Disease."

By unity of poison, I would beg my hearers to bear in mind I mean, not that the poison is always the same, but that the one poison—the one *origo mali*—whatever it may be, will originate several so-called different affections—widely different seemingly, widely different they would be spoken of, widely different even to be considered in every respect "specific."

The Gouty Kidney.

In the *Lancet*, January 12, 1884, we read that an interesting address was given to the Berlin Medical Society, at a recent meeting, by Professor Virchow (*Berl. Klin. Wochenschr.*, No. 1, 1884), upon the relations of gout and renal disease. He first of all dispelled the erroneous idea that gravel and calculus have anything to do with gout. He then showed that gouty—i. e., uratic—deposits often occur without the patient ever having been the subject of a definite acute paroxysmal attack of the disease; and he pointed out the distinctions between the chronic latent form and arthritis deformans, having only once met with the uratic deposit combined with the peculiar joint condition of the latter affection. The gouty condition depends on imperfect nitrogenous metabolism, and may either be due to the excessive ingestion of nitrogenous food, or to a special disposition to defective elimination of nitrogenous waste. The "gouty kidney" is characterized by a deposit of urate of soda within the tubules of the medullary portion; but the degree of the renal affection bears no constant relation to the amount of tophaceous deposit about the joints. Indeed, there may be no gouty arthritis present at all, and yet the kidneys be affected. It may be that there is an essential difference in these two classes of cases, but as yet no other condition than that known as the "gouty," and marked by an excess of urate of soda in the blood, is known to produce either the articular or the renal deposit. The kidney is also the seat of chronic interstitial nephritis—puckered and wasted—the wasting involving medulla as well as cortex. Virchow has never seen an *acute* nephritis which from the presence of the uratic deposit could be referred to gout. He points out that the chronic inflammatory change starts in the cortex, at a distance, that is, from the seat of the urates in the medullary tubes; just as in the joint, the urates occur in the cartilages and ligaments, whilst the synovial membrane is the seat of inflammation. From this he argues that it is not the presence of the crystals, but the exudation of the fluid containing the uric acid in solution, that

acts as the irritant; the surfaces in contact with the secretion that are inflamed, and not so much those in which the salt is finally deposited. And here he adduces as evidence an illness from which he suffered towards the close of 1882. He had never had any attack of acute gout, but from time to time he suffered from slightly reddened and painful swelling of the fingers, interfering with movement. In the course of 1882, he began to suffer from an irritable bladder, with occasional febrile attacks, which passed into considerable irritation of the urinary organs, with pyuria, ischuria, etc.; and he was made very uneasy by being told one day that in addition to the pus, albumen and renal tube-casts had been detected. The renal pelvis, bladder, and prostate—in fact, the whole urinary tract—seemed to be in turn affected by some irritant. One day he bethought him to examine the pus, which was passed in large amount, to determine its source, and to ascertain whether it came from a mucous surface only. On adding acetic acid to the deposit to ascertain the presence of mucus, he was surprised to see the whole microscopic field covered with uric acid crystals to an amount which he had never seen before. Yet there was no suspicion of gravel or calculus, and he rightly inferred that this excess of uric acid indicated energetic alkaline treatment. This he at once commenced, taking borate of soda and Carlsbad water, with almost immediate disappearance of the uric acid crystals from the urine. He continued the treatment for three months, and has never passed any pus, albumen, or casts since. He could give no other explanation than that the blood and urine being highly charged with urates in solution, had acted as irritants to the whole urinary tract, exciting a purulent catarrh—in fact, an inflammation analogous to that which occurs in gout when urates are deposited in the tissues. A few remarks upon the physical and anatomical differences between calcareous deposits in the kidney and the urates closed the communication.

The Influence of Bile in the Assimilation of Food in the Intestines.

The *London Med. Record*, January 15, 1884, says that C. Von Voit (*Centralbl. für die Med. Wiss.*, March 14), records his observations and experiments upon a dog, of seventy kilogrammes weight, having a fistula of the gall-bladder. The absorption of albumen, hydro-carbons, and fat, was noted, with the following conclusions:

1. The digestion and absorption of albumen in the form of meat was not interfered with by the outflow of bile. The nitrogenous constituents of the feces and of the urine were the same in amount as before the operation. A dog fed exclusively upon meat maintained the same proportion also of these constituents. The maximum amount of meat that was given did not affect the flow of bile.

2. The digestion of grape-sugar was not diminished by the presence of the fistula; the excretion of urea reached as high an amount as previously. An exclusively bread diet was as well digested; while the weight of the animal, and the proportion of nitrogenous elements, were the same as under a mixed diet of bread and meat.

3. The absorption of fat, on the other hand, was

notably affected by the existence of the fistula. Whilst, in the normal condition, 99 per cent. of fat would be absorbed, and only 1 per cent. appear in the feces; in the fistulous animal, only 40 per cent. was absorbed, and 60 per cent. was voided unchanged. Small quantities even of fat in the food interfered with its digestion; whilst larger quantities caused diarrhoea, borborygmi, and offensive flatus, and the evacuation of fat unchanged. The grey color of the stools in icteric disorders, the author considers, depends not upon the coloring matter of bile, but upon fatty matters therein contained. Further investigations were carried out upon two more dogs, in which fistula had been established. In one of these the bile was collected every hour, and the amount calculated for the twenty-four hours. In the case of the second dog, the whole quantity that flowed was collected together. With regard to the composition of the bile, it was observed that the proportion of the sulphur and biliary acids varied with the nature of the food, varying from 4.01 to 4.61 per cent. The nitrogenous elements of dry bile varied from 3.7 to 3.9 per cent. The fluctuations of the sulphur compounds were still greater. The proportion and the absolute quantity of solid matter in the bile varied with the amount and time of feeding, reaching the highest an hour afterwards, and depending, it would seem, upon a reflex flow of blood through the filling of the intestine.

REVIEWS AND BOOK NOTICES.

NOTES ON CURRENT MEDICAL LITERATURE.

—To those who care to turn once in a while from physic to metaphysics, from science to philosophy, we recommend a pamphlet by Prof. W. T. Harris, entitled, "Philosophy in Outline" (New York, D. Appleton & Co). It is from the pen of a master.

—The "Red Cross Class" of the Agassiz Association have commenced the publication of a series of little books or tracts to disseminate information as to the preliminary treatment of sickness or injury. The first has reference to the treatment of fractures, carrying the wounded, bandaging, etc. (Address Dr. C. E. Warren, 51 Union Park, Boston, Mass.)

—Two numbers of the *Revue d'Hydrologie et de Climatologie Pyrénéennes* have reached us. It is a new journal, published at Toulouse, France, and will be interesting to hydrologists.

—The Proceedings of the Clay County, Mo., Board of Health make a closely printed pamphlet of 13 pages, containing the address of the President, Dr. J. M. Allen; an essay on Water, by Dr. J. R. Eaton; and a paper on Epidemics, by Dr. J. L. Jones. Such publications cannot fail to be a benefit to the community.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium. - - - -	6.00
Physician's Daily Pocket Record, - - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

INTESTINAL OBSTRUCTION.

Two cases recently reported to the Suffolk District Medical Society (*Boston M. and S. Jour.*), by Dr. John Homans, bring this question so prominently before us, that a few words on the subject will be appropriate and valuable.

A discussion on this subject at the last meeting of the British Medical Association, participated in by men of great experience, resulted, as might be supposed, in great diversity of opinion, some holding that early operative interference is called for in all cases of intestinal obstruction, while others of equal experience relegate it to a position after all other means have been tried and failed.

To an impartial reader of the various opinions on the subject, it would seem that the best treatment is that which, to a certain extent, is based upon the cause of the obstruction. Of course, it is impossible, in the majority of cases, to definitely decide the cause and the location of the cause, save by exploratory incision; but we usually can approximate it, that is to say, we can decide whether it is due to some trouble that threatens the rapid death of a portion of the gut, or whether the obstruction is due to some slow-proceeding cause, that will not be badly prejudiced by waiting. This will be made apparent to us by the presence or absence of constitutional symptoms.

In the two cases reported by Dr. Homans, the only symptoms were those produced by the retention of faecal matter in the system, such as general depression of the vital forces, but there were no acute symptoms; no pain (of any moment) no faecal vomiting, no fever nor acceleration of pulse; hence he waited until all other measures had failed, when, upon opening the abdomen, he found (in both cases) cancer of the descending colon, near the rectum, which completely occluded its calibre. Artificial ani were made, and in one case the patient survived for ten months, ultimately succumbing to the results of cancerous deposits throughout the mesentery and omentum; in the other case, where the operation had been more protracted, and the handling of the intestines much greater, the patient died five hours after operation.

It would seem then that when with non-passage of *feces* we have high temperature and pulse, great pain and the usual indications of rapidly approaching damage to the intestine, we should cut down, and if we find the obstruction removable, as an invagination, a twist or a constricting band, remove it; while if it is due to cancer or some irremediable cause, we can make an artificial anus.

But when we do cut down, it seems to us very important that we should search until we have found the cause, rather than to accept Mr. Lawson Tait's advice to make an opening into the first loop of intestine that presents itself. Mr. Tait is an exceedingly high authority; but let us suppose that a cancer, causing the obstruction, exists at a point *between* the stomach and the first loop of intestine that presents—we cannot see how the patient's condition will be benefited by making the artificial anus at this point; while, again, experience demonstrates that when the opening is made high up in the intestine, the patient is much more likely to suffer from gradual emaciation and loss of strength, as might be expected from the abolition of a large portion of the digestive and absorptive surfaces of the body. In one of Dr. Homans' cases there was absolute obstruction for *seven weeks*, which strengthens the arguments for the expectant plan when urgent acute symptoms are not present. The intelligence of the surgeon must guide him in the treatment of intestinal obstruction, just as in all other matters, for no definite absolute rules for his guidance can be laid down.

A case suitable for operation is reported in the *Medical Age*, February 11, 1884. Here, as the result of a kick, peritonitis and obstruction occurred. Abdominal pain was intense and localized, there was stercoraceous vomiting, while enemas only brought away blood and coagula. The autopsy revealed invagination of the *cæcum*, the lower end of which had sloughed. In this case, cutting down, excising the gangrenous gut, and stitching together the healthy intestine, would have been a justifiable operation, and *might* have saved the boy's life.

ASTOUNDING MEDICAL LEGISLATION.

Of all the schemes to promote the deterioration of the medical profession by injudicious patronage, the most astounding is one that was lately introduced into the Virginia Assembly. The text of the bill runs as follows:

1. Be it enacted by the General Assembly of Virginia, that the sum of seven thousand five hundred dollars be and the same is hereby appropriated out of the treasury, as an annuity to the Medical College of Virginia, to be expended under the direction of the faculty of said college, who are hereby required to report annually to the Governor an account of the disbursement of the said sum of money.

2. That there shall be admitted to the said Medical College of Virginia, while this annuity is paid, free from all charge for tuition, except the sum of five dollars as a matriculation fee, as many students who are citizens of Virginia as there are members of the General Assembly, each member of which is hereby empowered to nominate, in each year, from his county or district, a student to the faculty of said college, who may prescribe the academic qualifications of the nominee.

The plan of "beneficiary students," as practiced by some medical colleges, notably one in Kentucky, is bad enough; but this scheme, which enables every member of the General Assembly of a State to appoint for free instruction every year some young man, is still more surely calculated to lower the standard of medical qualifications and work injury to the profession.

It has been cogently observed by a writer on this question that if free instruction is to be given to young doctors, why not to young aspirants to the bar? why not to clergymen? to civil and mining engineers? If *professional* men of any class are to be furnished for their special business—equipped for their life work—at State expense, why not have commercial and business colleges for clerks, and so on, without end? The *principle is wrong*. Public education can be justified only on the ground, that the citizen by being taught the elements of education is thereby better fitted to meet and discharge his duties to society *as a citizen*, in those functions which are common to all citizens. This reason utterly fails to apply to

professions and professional education. They are *special*, and *individual*, by the very terms of the statement—and therefore outside of the reason which vindicates public school instructions for the masses.

No one man has any claim on the public to be furnished with a business, or to be qualified for it, beyond every other man.

Gratuitous professional instruction at the public expense, is therefore a violation of common right, and a misapplication of the public money.

Already the excess of professional men in proportion to our general population has caused serious reflections, and this bill aims to make it worse.

The question is not a local one. It is not one of Virginia State politics. The medical graduates of her colleges have rights all over this country, and we claim that no State should flood our land with half-educated professional men.

EARLY OPERATIONS.

Far be it from us to advocate the unnecessary use of the knife, which is always a serious matter even in the most trivial operations, and one to be carefully considered in all its possible consequences, and the arguments pro and con to be carefully weighed; but the thought has been suggested by some recent remarks, whether our surgical results would not be much more satisfactory, if, when ultimate operation is inevitable, it be performed early, before the diseased process has assumed much magnitude, and before any implication of the system has occurred.

We have already noted Jonathan Hutchinson's advice about operating in what he felicitously styles the pre-cancerous stage of cancer, and we have laid stress upon Professor Gross' remarks "On Early Operation in Morbid Growths;" while now Dr. Goodell tells us that our women are very averse to being operated upon (for ovarian disease), hence their proneness to delay matters until they have become very weak.

To what do these remarks of eminent and experienced men point? To early operation; to the

removal of the nidus of death, before the system has become seriously impaired, and while the strength is of such a standard as to offer a reasonable hope that the results of the operation will not prove serious.

When a woman, whose age and family history make us think of cancer, presents herself with a nodule in the breast, would it not be proper to at once cut it out? In the majority of cases the operation would be but a trivial affair, even if the lump was *not* cancer, while the chances for radical restoration to health would be much greater than if we had waited for the nature of the disease to be made manifest to our senses as cancer, when the whole body would be probably more or less cancerous, and the system robbed of much of its vital power. The same rule would hold good in all diseased processes, wherein there is a probability that operative interference will be demanded at some more or less remote period, when the prospects for a successful issue will be diminished by this policy of delay.

PUERPERAL FEVER.

In a recent issue we gave a report of a most admirable address on the prophylaxis and treatment of puerperal fever, by Dr. T. Gaillard Thomas, of New York.

The views therein expressed have occasioned considerable comment among the professional brethren of Dr. Thomas, and a recent meeting of the New York Academy of Medicine was enlivened by a discussion of the paper, in which we regret to say that personalities, ostensibly in the form of good-natured repartee, but to an unbiased reader sounding very much like undignified insinuations, were indulged in between Drs. Thomas and For-dyce Barker. Aside from these personalities, the discussion is possessed of sufficient importance to warrant comment.

It will be remembered that Dr. Thomas maintained that puerperal fever is puerperal septicæmia, caused by the entrance of disease germs through some rent or tear that has occurred to the parturient parts during labor.

To this Dr. Barker does not accede, claiming

that while there is a puerperal septicæmia, yet puerperal fever is a disease *sui generis*—whether due to the introduction of a specific germ or not, he does not state. But the most important point on which Dr. Barker differs from Dr. Thomas, and in which most of those who participated in the discussion supported Dr. Barker, was as to Dr. Thomas's recommendation for the use of antiseptic vaginal and uterine injections as prophylactics. Dr. B. and his adherents claimed that not only did experience prove that they were not necessary, but that they are absolutely injurious, as affording a ready and frequent means for the introduction of disease germs. For the past two or three years Dr. B. has absolutely abandoned vaginal injections in normal cases, and his results have been more satisfactory than previously. After hearing the expressions of opinion, Dr. Thomas seemed inclined to modify if not to abandon this particular recommendation, though he still adhered, as did most of those present, and as will every sensible man, to his other recommendations, which, as we said at the time, really consist in scrupulous cleanliness of physician, patient, and attendants.

RUNNING FOR TRAINS.

We have just missed a train, and we missed it because we would not run.

This experience suggests to us to offer a few words of advice, through our readers, to the busy men of America who are in a chronic state of "*running for trains.*"

Even to one whose heart is sound, running, when not accustomed to such hurried movement, is certainly not beneficial to the delicate cords and valves of the heart; and should this organ be diseased, it must prove very injurious.

We all know that violent and tumultuous action is to be avoided when the heart is weak, and we also know that running is not the way to avoid it.

In our own experience we know several instances, where men who had previously supposed themselves to be *sound* have run for trains, and getting aboard have fallen exhausted into seats

from which they have been removed as corpses; and knowing such cases, we *never* run for trains.

Better miss a train than run the risk of running into the jaws of death; for this strain on the heart cannot prove beneficial to one that is sound, while it most positively will prove more or less disastrous to one that is weak. In this world of unsuspected physical pitfalls, it behooves us "*to make haste slowly.*"

NOTES AND COMMENTS.

"Miryachit" and "The Jumpers."

Dr. William A. Hammond, in a paper read before the New York Neurological Society, described a peculiar disease that is not uncommon in Siberia, and is known as "*Miryachit.*" It is characterized by excessive imitation, that is to say whatever the patient sees anybody else do, he at once does the same. To illustrate:

"We afterward witnessed an incident which illustrated the extent of his disability. The captain of the steamer, running up to him, suddenly clapping his hands at the same time, accidentally slipped and fell hard on the deck; without having been touched by the captain, the steward instantly clapped his hands and shouted, and then, in powerless imitation, he too fell as hard and almost precisely in the same manner and position as the captain."

This disease brings to mind the remarks made by the late Dr. George M. Beard, before the meeting of the American Neurological Association, in 1880, relative to the "*Jumpers*" or "*Jumping Frenchmen*" of Maine and northern New Hampshire.

In June, 1880, Dr. Beard visited Moosehead Lake, found the "*Jumpers,*" and experimented with them. He ascertained that whatever order was given them was at once obeyed. Thus, one of the jumpers who was sitting in a chair, with a knife in his hand, was told to throw it, and he threw it quickly, so that it stuck in a beam opposite; at the same time he repeated the order to throw it, with a cry of alarm not unlike that of hysteria or epilepsy. He also threw away his pipe, which he was filling with tobacco, when he was slapped upon the shoulder. Two jumpers standing near each other were told to strike, and they struck each other very forcibly. One jumper, when standing by the window, was suddenly commanded by a person on the other side

of the window to jump, and he jumped up half a foot from the floor, repeating the order. When the commands are uttered in a quick, loud voice, the jumper repeats the order. When told to strike he strikes, when told to throw he throws whatever he may happen to have in his hand. Dr. Beard tried this power of repetition with the first part of the first line of Virgil's "*Æneid*" and the first part of the first line of Homer's "*Iliad*," and out-of-the-way words of the English language with which the jumper could not be familiar, and he repeated or echoed the sound of the word as it came to him in a quick, sharp voice, at the same time he jumped, or struck, or threw, or raised his shoulders, or made some other violent muscular motion. They could not help repeating the word or sound that came from the person that ordered them, any more than they could help striking, dropping, throwing, jumping, or starting; all of these phenomena were indeed but parts of the general condition known as jumping.

I am not able (says Dr. Hammond) to give any certain explanation of the phenomena of "*Mir-yachit*" or of the "*Jumpers*," or of certain of those cases of sleep-drunkenness which seem to be of like character. But they all appear to be due to the fact that a motor impulse is excited by perceptions without the necessary concurrence of the volition of the individual to cause the discharge. They are, therefore, analogous to reflex actions, and especially to certain epileptic paroxysms due to reflex irritations. It would seem as though the nerve-cells were very much in the condition of a package of dynamite or nitro-glycerin, in which a very slight impression is sufficient to effect a discharge of nerve force. They differ, however, from the epileptic paroxysm in the fact that the discharge is consonant with the perception—which is in these cases an irritation—and is hence an apparently logical act, whereas in epilepsy the discharge is more violent, is illogical, and does not cease with the cessation of the irritation.

Certainly the whole subject is of sufficient importance to demand the careful study of competent observers.

Tuberculosis of the Testes.

To the New York Pathological Society (meeting January 9, 1884), Dr. A. G. Gerster presented the testes of three different patients which he had recently removed for acute tuberculosis. The first specimen was from a laborer, thirty-eight years old, who was recognized to have a hydrocele, but

whether simple or dependent upon disease of the testicle was not at first determined. There was no known cause for the condition; he denied venereal disease. Volkmann's operation for hydrocele was successfully performed, the wound healing in a perfectly normal manner; but, five weeks after his dismissal from the hospital, the patient returned, saying that he had passed a bad night, had had a chill, and had begun to lose flesh and strength. The testicle was then extirpated, and was found to show central tuberculosis, the hard, characteristic tubercular mass not yet having begun to break down. The second specimen showed a slightly more advanced stage of the disease, and was from a man thirty-one years of age, who had suffered acute orchitis and epididymitis of traumatic origin. Six or eight weeks after the injury the testicle was painful, swollen, and hard, the swelling extending up the cord some distance. The patient suffered chilliness and sweating, and presented a condition demanding removal of the testicle, which was done. The chief interest of the specimen related to the condition of the tunica vaginalis, which, instead of being smooth and hard, resembled very much the synovial membrane in cases of tuberculosis of the joints. There was incipient breaking down of the tuberculous deposit centrally. In the third case there had been chills, emaciation, loss of appetite, and swelling and pain of the testicle, and, on removal, the organ was found to consist almost entirely of broken-down tissue; the tunica vaginalis had become obliterated. Dr. Gerster remarked that the diagnosis could be made much earlier in these cases than was formerly done, and lead to proper treatment in the way of extirpation, whereas it used to be the practice to let the condition remain until a fistulous opening formed in the scrotum, and the case reached the state falsely called *hernia testis*. In the discussion which followed, Dr. Gerster said that there had been no physical signs of tuberculosis in any of the other organs of the body. The other general symptoms—chill, sweats, etc.—disappeared on removal of the diseased testicles.

Slop Diet.

There can be no question in the mind of any thoughtful man that diet must have a great influence upon the course of disease processes, hence it is that we note the following reply, in the *Lancet*, January 12, 1884, to one who writes to inquire more fully about slop diet:

The objects aimed at in giving slop diet may be—(1) depletion of the system by cutting off the

supply of nitrogenous and combustible material ; (2) the securing of rest to the digestive organs ; (3) the avoidance of the ills which follow upon the taking of food upon which the digestive and assimilative organs are unable, through debility or actual disease, to exert their full function. Experience has shown that cutting off all food from healthy men causes death in about five days, and is attended with great suffering. If water alone be allowed, the suffering is very greatly lessened, and life can be prolonged for about the same number of weeks. The introduction of water entails no "work" upon the digestive or assimilative organs, and therefore it admirably fulfils the conditions of "slop diet," whether required for any one of the three objects mentioned above. It is therefore the best "slop diet," and we believe that as such it is not sufficiently appreciated by the profession. Saline solutions stand next in order of merit, requiring no "digestion," and undergoing little, if any, change when passing through the assimilative organs. Saccharine solutions must rank next; they are readily absorbed, but possessing distinct nutritive value, they are not so depletive as water, and, moreover, being liable to undergo fermentation in the alimentary canal, they do not afford such complete rest to that organ. They also have the disadvantage of being less palatable than the former. Decoctions of starch require distinct "digestion" and "assimilation," possess high nutritive value, if unabsorbed are liable to fermentation, and may leave a considerable residue of undigested matter to pass along the intestines. Solutions of albumen must be placed at the bottom of the list, as requiring digestion and assimilation, and as possessing the highest nutritive value, being "tissue-forming" as well as "force-producing."

Acute Pyæmia of Urethral Origin.

To the New York Surgical Society (*Med. News*, December 22, 1883,) the President (Dr. R. F. Weir) presented kidneys and heart illustrating acute pyæmia of urethral origin. They were removed from the body of an apparently healthy man, twenty-five years of age, who had been subject to gleet discharges traceable to stricture. He had had instruments passed from time to time during the summer and in the autumn. Last Sunday his attending physician introduced a sound, No. 23 French, which passed into the bladder without violence, and with no more difficulty than had been produced on all the other occasions. A few drops of blood escaped. On Mon-

day the man was seized with a severe chill. When Dr. Weir saw the patient he had a temperature of 105° F., and he supposed it to be due to malaria, as he knew that the patient had suffered formerly from such chills, which had invariably yielded to quinine. The temperature, however, remained high, and within forty-eight hours afterwards he began to develop joint pains and effusions. He complained of no distress in the bladder, but said that once or twice he had noticed that the urine was very slightly tinged with blood. The man became so delirious that he was removed to the hospital, where he died twenty-four hours afterwards. Before death, evidence of pericarditis and endocarditis was detected, and the opinion was formed that it was pyæmic. At the autopsy multiple infarctions with grayish centres were found in the cortex of the left kidney, the right being comparatively unaffected. Pericarditis and recent valvular disease, with excavation at base of one of the cusps (ulcerative endocarditis), were found, and infarctions in the centre of the substance of the heart. The rapidity of the course of the case was especially interesting. Dr. Weir had not seen in acute pyæmia heart lesions so distinctly marked as in the present instance. There were no lacerations of the urethra, but evidences of croupous cystitis were present.

Tubercular Peri-urethritis.

From the *Centralb. für Chirurgie* we learn that at the recent Congress of German Naturalists and Physicians, Dr. Englisch presented a paper with this title. The disease, he says, begins as an inflammatory tumor in the bulbous portion, usually as an inflammation surrounding the urethra, or involving Cowper's glands. It extends constantly, as well toward the surface, leading to perforation of the skin, as in other directions toward the urethra, prostate gland, rectum, or epididymis. The urethra is often perforated, usually at the junction of the bulbous and membranous portions, though sometimes in the pendulous part. The disease is characterized by a growth of fungous granulations resembling very closely those seen in tuberculosis of the articulations. It occurs in tubercular and tubercularly disposed individuals, and may arise from urethritis, specific or otherwise, injuries of the urethra or perineum, or anything which occasions or is accompanied by inflammation. The course of the disease is usually slow, yet in some cases it is quite rapid. If there is already a pulmonary affection it now progresses more quickly, and if none has existed it is now developed. Since the fungous granulations

present great resistance to all modes of treatment, there is but little to be accomplished in the way of cure. New granulations are continually formed, and any attempts to close the fistula are unsuccessful. The retention of a catheter for a sufficiently long time to allow of their closure, is rendered impossible by reason of the quickly-produced vesical catarrh. Hence the therapy is narrowed down to attempts at improving the general condition by means of constitutional remedies.

A New Method of Strapping for Hydrocele.

To the Suffolk District Medical Society (*Boston M. and S. Jour.*, February 14, 1884), Dr. J. C. Warren showed a chamois-leather bag which he had devised for the purpose of exerting pressure on a small collection of fluid left in the tunica vaginalis remaining after an operation for radical cure. The bag can easily be applied by isolating that portion of the scrotum containing the testicle to be compressed and forming a pedicle, which is preserved by tightening the chamois-leather string. The bag is then laced from above downwards, and if it has been made to fit snugly, exercises a gentle and equable pressure. If it is

LEACH & GREENE,
BOSTON.

necessary to increase the pressure, a few turns of a common narrow roller bandage around the equator of the globular mass are all that is necessary. This bag is free from the well-known discomforts of plaster, is easily made and applied, and can be removed and re-applied by the patient himself as often as is desirable, thus avoiding excoriation at constricting points. In the single case in which it was used the effusion promptly disappeared, and has not since returned at an interval of nine months.

The Brain and its Influence on Mental Faculties.

The *Brit. Med. Jour.*, January 19, 1884, says: A recent discussion on the weight of Turgeneff's brain has called the attention to the subject of human brains, and a scientist, M. Nikiforoff, has published in the *Novosti* an article, in which he

states that the weight of the brain has no influence whatever on the mental faculties. The average weight of a man's brain is, according to Luschka, 1,424 grammes, of a woman's 1,272 grammes; Krause gives the averages as 1,570 and 1,350 respectively. The maximum weight is said to be 1,600 grammes, and the minimum 800 grammes. The brain of the celebrated mineralogist, Hausmann, weighed 1,206 grammes. It ought to be remembered that the significance of the weight of the brain should depend upon the proportion it bears to the dimensions of the whole body, and to the age of the individual. Byron died at the age of thirty-six—the great geometrician, Gauss, at seventy-eight years of age; the brains of the two should, therefore, not be compared. It is equally important to know what was the cause of death, for long disease or old age exhaust the brain. To define the real degree of development of the brain, it is, therefore, necessary to have a knowledge of the condition of the whole body; and as this is usually lacking, the mere record of weight possesses little significance.

Modifications in Muscular Structure after Nerve-Section.

From the *Rev. Scientifique*, January 12, 1884, we learn that M. Babinsky has recently presented a communication on this subject to the Académie des Sciences. These modifications consist essentially of simple atrophy of the contractile substance, with multiplication of the sarcolemma cells. Babinsky shows that atrophy of the contractile substance progresses in direct proportion to the development of the protoplasmic structure; this dissociates the primitive cylinders, and thus brings out the field of Cohnheim much more distinctly than in the normal state; it accumulates in certain fasciæ, at their periphery and between the sarcolemma and the striated substance, in other fasciæ at their central part, so that the striated substance is turned back toward the sarcolemma. This last disposition is particularly interesting, because the altered muscular fibres are exactly similar to muscular fibres in process of development.

Experiments on the Pneumogastric Nerve.

Before the Academy of Medicine in Ireland (*Brit. Med. Jour.*, January 26, 1884), Dr. Scott read a preliminary communication concerning experiments on the central end of the pneumogastric nerve. In some experiments performed by Dr. Purser and himself on the central end of the vagi, certain facts were observed differing from

those hitherto described. First, on section of one vagus, the heart-beat was not retarded, but there was a slight fall of blood-pressure; secondly, on section of the vagi, a considerable rise of pressure ensued, associated with a retardation of the heart-beat, these being independent of the stoppage of respiration. The foregoing facts would show that the heart was inhibited by other means than the vagi. The respiration also was differently affected when one or both vagi were divided. In the former case, the stoppage was always followed by expiration; in the latter, by inspiration.

The president testified that the tracings exhibited were accurate copies of the original tracings. They were very curious in a great many respects, and the phenomena were extremely complicated, indicating not only the action on the nerves, but the influence produced by the asphyxia.

Dr. Scott, in replying, observed that it was only after the section of both vagi that the beats made their appearance.

The Relation of the Medulla to the Sexual Function.

In the *Practitioner*, February, 1884, Dr. Alexander Harkin advances arguments in favor of Van der Kolk's notion that this part of the nervous system is particularly related to the genital function; and believes there to be a "sexual centre," as well as "respiratory," "convulsive," and other centres in this region. He points out the association between sexual excess and neurotic affections, notably epilepsy; and thinks there is good reason for the belief that so-called "neurasthenia spinalis" and "abnormal seminal losses" depend on a congested state of the medulla. He selects three cases in which the symptoms of these conditions were very marked, in each of which striking relief and even cure was effected by wet cupping over the nape of the neck. Cold douches in the same region, and the administration of bromide of potassium and belladonna, are often, he says, as effectual. Dr. Harkin's views are certainly worthy of consideration; and his line of practice, combined with precepts intended to strengthen the will and improve the physical condition, is one which should not be disregarded in dealing with those unfortunate subjects of a hypochondriasis induced by perverted and unnatural sexual excitation.

The Thirteenth Cranial Nerve.

The *Lancet*, February 2, 1884, says: Regarded physiologically, the chorda tympani hardly seems to be a branch of the facial nerve. Dr. Sapolini,

of Milan, has been working at the anatomy of the chorda tympani, and comes to the conclusion that it must be regarded as a nerve *sui generis*. He believes it contains motor and sensory fibres. Its deep origin is placed about the posterior end of the floor of the fourth ventricle, whence it traverses the floor of this ventricle in a forward direction. It leaves the surface of the pons Varolii quite close to the auditory nerve, with which it exchanges many filaments. The nerve, once at liberty, is composed of two filaments, and is embraced by the seventh and eighth nerves, with which it pursues its course through the internal auditory meatus and the geniculate ganglion. The rest of its course, under the name of the chorda tympani, is well known.

The Physiology of Deglutition.

Some admirable studies on the phenomenon of swallowing were published recently in Berlin by the Physiological Institute from the pen of Dr. S. Meltzer, now of New York city. One of these was with reference to the mechanism of deglutition, its causation and suspension, the other on the irradiation of its action, and the general import of the act.

These essays are not only excellent examples of physiological research, but their author has given them practical applications. He finds, for instance, that swallowing increases cardiac action and derives from this some sound precepts for the treatment of fainting. In severe choking and coughing spells, rapid and frequent swallowing will relieve the local irritation. We hope this investigator will continue his researches.

An Inhalation for Catarrh, Coryza, Asthma, etc.

M. St. Martin recommends this formula in the *Jour. de Med. de Paris*:

	Parts.
Acid. carbolic,	5
Ammon. pur. liq.,	6
Aque dest.,	10
Alcohol,	15

Soak some cotton wool with this mixture, and breathe this vapor from a wide-mouthed bottle.

Acute Aortitis.

In the *Gaz. Med. de Paris*, M. Peter gives the following diagnostic points in this disease:

An agonizing pain at the level of the preaortic region; a burning sensation, sometimes excruciating; and a dyspnoea, which is never wanting, and which is especially characteristic, because on auscultation of the respiratory organs nothing can be discovered to account for it.

SPECIAL REPORT.

NO. XVI.—OPHTHALMOLOGY.

BY C. S. TURNBULL, M. D.,

Oculist to the German Hospital, Philadelphia.

(Continued from page 318.)

Sattler also introduced lochial secretion into the eyes of an infant. After forty hours blennorrhœa developed. This proves by direct experiment that blennorrhœa is due to infection with lochial secretion, and that the conjunctival sac of the new-born is the best soil for breeding the micrococci of blennorrhœa, when in a mixture of various kinds of bacteria. Probably the micrococcus of blennorrhœa floats about the air. It enters the vagina, there undergoes a sort of preliminary culture, and thus acquires the peculiar power of producing, under certain favorable conditions, a blennorrhœic inflammation in the male urethra, and the conjunctiva. The most rational form of treatment would, therefore, seem to be the antiseptic.

Cas d' Auto-inoculation Vaccinate ayant Donné lieu a une Ophthalmic Diphthero-purulente.

Fifty-six days after the development of a vaccine pustule on his own arm, Stocquart observed purulent conjunctivitis in the left eye, followed by false diphtheritic membranes on the conjunctiva. Cured by antiseptic treatment. Probably some of the vaccine had got into his eye, as with the exception of the arm and eye no other part of the body was affected.

The Treatment of Gonorrhœal Ophthalmia. The Lancet, October 14, 1882, p. 345.

In three cases of gonorrhœic ophthalmia, Bader obtained good results by the use of a salve consisting of one grain of red precipitate and one-fifth of a grain of atropine, to an ounce of vaseline.

Simi (*Sulla Ophthalmia Purulenta Provocata come un Mezzo Terapeutico.* Bell. d' Ocul., vol. v. 3, November, 1882,) favors the inoculation of blennorrhœic pus in cases of pannus. In a view of the excellent result frequently obtained, so powerful a remedy should not be simply discarded. The danger to the cornea from blennorrhœa seems the less to the author, the denser the pannus which protects the healthy parts of the cornea like a coat of mail at the height of the inflammation. If jequirity should meet expectations, he would, of course, prefer it, as the intensity of the inflammation could be regulated.

Dianoux (*De l' Ophthalmie Purulente Provoquée comme Moyen Therapeutique.* Le Prog. Med., 1882, Nos. 41 and 43,) reports two cases of granular

pannus, and one of total sclerosis of the cornea, which were cured by the inoculation of blennorrhœic pus. In the latter case improvement was very moderate. Dianoux hopes to produce a milder form of blennorrhœa by inoculation with Neisser's cultivated micrococci, and believes that obstinate cases of trachoma with intact cornea could be cured by such an inoculation.

L' Ophthalmia Purulenta Artificiale Prodotta dal Jequirity. Boll. d' Ocul., vol. v. 3, Nov., 1882.

Moyne was the first in Italy to make experiments with jequirity. For three days applications were made with an infusion of jequirity (32 pulverized beans to 1,000 grms. of water) to the eyes of three children suffering from trachoma, who had been treated for four months with nitrate of silver and tannine without much success. In one case there was considerable reaction; the lids swelled, the cornea became slightly hazy, and on the fifth day purulent secretion set in. This state of affairs soon ended, and on the twentieth day all the symptoms, as well as the trachoma, had disappeared. In the other two children the inflammation was much milder, nevertheless the granulation soon disappeared. In all three cases the cornea was not pannous.

Jequirity. Boll. d' Ocul., vol. v., 4, December, 1882.

Simi tried jequirity according to Wecker's method, in two cases of trachoma and pannus. Inflammation set in, as expected, and culminated on the fourth day; on the twelfth day it came to an end. As regards the result, no change could be seen in one patient, one of whose eyes was staphylomatous, and the other partly so, either in the trachoma, which had existed for four years, or in the pannus. In the other patient the granulations had become smaller, while the pannus had not perceptibly diminished, though the patient declared he could see better.

Snell, Ophth. Rev., vol. i., Oct. 1882, p. 346, obtained good results with boracic acid in purulent catarrhal, and some kinds of phlyctenular ophthalmia. According to the intensity of the inflammation, he uses a stronger or weaker solution (10–25 grains to the ounce).

Ferguson, Ophth. Rev., vol. i., Nov. 1882, p. 363, recommends boracic acid in acute catarrhal and purulent ophthalmia. He uses it thus: After carefully ectropionizing the lid, boracic acid, in the form of an impalpable powder, is dusted upon and then washed off. If the action is too severe, he employs a solution.

Landolt, Arch. d' Ophth., reports in detail on the production of hydrogen dioxide, its physical and

chemical properties, its physiological action and its importance as an antiseptic. It acts as such by setting free oxygen in a nascent state, directly destroying the bacteria, and mechanically disintegrating the pathological products, and thus aiding their removal. He recommends it diluted with water, especially in purulent conjunctivitis, old corneal ulcers, and purulent affections of the lachrymal apparatus, in all of which he obtained good results. It produces no pain, and has no injurious influence on the eye, provided the preparation be pure, for controlling which he gives the necessary reactions.

Magnus, Klin. Monatsbl. f. Augenheilk., vol. xx., p. 396, extracted a bit of glass from the cornea of the left eye of a lady, which had been there for two years and three months without causing any marked irritation.

Pathogénie des Kystes de l'Iris. Leur Production Artificielle par des Greffes de Lambeaux de Cornée sur la Membrane Iridienne. Acad. des Scienc., Jan. 15, 1883 :

Masse continued his experiments on rabbits for the artificial production of cysts of the iris. He introduced a small piece of cornea, abscised with Beer's knife, into the anterior chamber, where it attached itself to the iris and became opaque and vascular, the blood-vessels coming from the iris ; genuine cysts with transparent walls then developed, which undoubtedly grew out of the corneal tissue transplanted upon the iris.

(Basel.) *Un Cas de Tuberculose de la Choroïde, Inoculée dans la Chambre Antérieure de Lapins.* Arch. d'Ophth., vol. ii., No. 6.

Hirsch experimented upon the eyes of rabbits in regard to inoculation masses of the choroid. He enucleated the right eye of a young man of seventeen, without any hereditary taint, which gradually had lost its sight after nutritive disturbances, while a tumor gradually developed to the inward of the cornea, whose nature could not be definitely determined. From this tumor a fistula extended inward to a cavity occupying the greater part of the interior of the eye, the walls of which consisted of a caseous mass, which included the deeper layers of the sclera and most of the choroid, while only the anterior and a small part of the temporal section of the eye was comparatively healthy. This caseous mass was introduced into the anterior chamber of three rabbits, where it produced an eruption of tubercles on the iris after the lapse of twenty-two to thirty-nine days. These tubercles, when used for inoculation, produced the same result after twenty-three days. Unfortunately, the experiments could not

be continued, as all the animals perished by an accident. In the inoculated tubercles, neither giant-cells nor tubercle bacilli were found. Nothing abnormal in the thorax or abdomen.

Recherches Microscopiques sur les Ossifications Choriodiennes. Rec. d'Ophth., Dec., 1882.

Hoene gives the microscopical description of two cases of bone-formation in the choroid. Hoene thinks that bone develops in the choroid in embryonic tissue, which is the product of exudation of the choroid. This exudation becomes organized, is changed to connective, and finally to bony tissue. The precise localization, and the relation of the osseous tissue to the choroid, therefore, depend only on the intensity and localization of the inflammatory process.

On Cataract and Other Affections of the Eyes in Persons Struck by Lightning. V. Graef's Arch. f. Ophth., vol. xxviii. 3, p. 255.

Leber reports the case of a sea captain of thirty-one, who had been struck by lightning, burning the skin of the left side of his body down to the thigh, and producing total hemiparesis of that side. After these affections had been cured, cataract developed in both eyes in the course of a few months, in the left more than in the right, while there was also partial atrophy of the optic nerve, mydriasis, paralysis of accommodation of that eye. The result of the operation was comparatively good. Five similar cases of cataract were found in searching through the bibliography, eight cases of amaurosis in pre-ophthalmoscopic times, and periodic amaurosis or amblyopia respectively in four cases, among them the interesting one of Reich, of rupture of the choroid. Generally both eyes are affected, rarely (Sæmisch) only one. The electric discharge is the cause of all these affections, no matter whether lightning strikes the body itself or only passes close to it. The direct physical, chemical, catalytic action of the electric discharge upon the lens is the cause of the cataract.

Benson reports a case of *cholesterine cataract* in a child a year old, whose entire lens was a mass of bright yellow crystals.

CORRESPONDENCE.

Ergot in Convulsions.

EDS. MED. AND SURG. REPORTER :—

In a recent number of the MEDICAL AND SURGICAL REPORTER I noticed a short note from Dr. A. N. Carrigan, Washington, Arkansas, in which he speaks of the good effects of ergot in convulsions; and I wish to add my mite corroborative. Strange indeed, in the discussion referred to, none of the

eminent men present should have alluded to the drug at all, when it exercises such an influence over (almost) all forms of convulsions. In the puerperal variety, my experience with it, in combination sometimes with morphia, has been most satisfactory; and in the convulsions of children, with or without the last-named drug, nothing that I have used has been so reliable. In the latter variety I have never had to give more than two doses hypodermatically, with appropriate after-treatment to restore the patients.

Case after case could be reported to show its efficacy, but will only give the outlines of one. On August 11, 1883, was called in the afternoon to see Emma F., aged three years, and found her in a convulsion, and learned that she had had them every few minutes from about 8 a. m., in a very severe form. As soon as possible I inserted twenty drops fl. ex. ergot in her arm, and in a short time had the satisfaction of seeing an improvement in her condition. Another insertion half an hour afterwards restored her to perfect consciousness, when, after giving necessary medicines for the cause (irritation from worms, and costive bowels), I left, to find her sitting up on my return next day.

Two cases of the puerperal form have been brought to a safe termination with it; one requiring morphia to be added, the other, and seemingly the worst, not. Let others try the remedy, and report their experience. Yours truly,

A. L. PURDOM.

Hickory Creek, Ark., Feb. 18, 1884.

NEWS AND MISCELLANY.

Fortunes Made by Charlatans.

The *Pacific Med. and Surg. Jour.* very wisely says that it is not surprising that crafty men who love money more than virtue and truth, should go into the nostrum trade when they behold the fortunes that are sometimes made by an ingenious mixture of fraud and physic. Most persons have noticed the advertisement of "Dr. Parr's Life Pills," with a cut of the venerable old gentleman, whose association with the pills is as foul a slander on his memory as the cut is a burlesque on his true figure. Those pills were a fabrication of Mr. Ingram, the founder and late proprietor of the *London Illustrated News*, who made his fortune by the fraudulent speculation. Through his wealth thus accumulated he gained a social position in society, and finally procured his election to Parliament. He used to say that having noticed that purchasers generally gave preference to goods advertised with a cut, he took the hint and fabricated a cut of Dr. Parr in connection with the use of his name, and that this proved an element of success in his pill business. We have in California a number of adventurers in the same field who employ the same trick, sometimes varying it by supplying the portrait with their own cheeks. As a rule, this class of advertisers hold the first rank as impostors and put forth the most unblushing falsehoods. We do not know, however, of any one who has succeeded like Mr. Ingram in gaining a foothold in good society. It is not uncommon for men or women of high stand-

ing to patronize quacks, despising them at the same time. If they recognize the pretended "doctors" in social life, such men as Li-po-tai would have the run of a number of aristocratic dwellings in San Francisco. The experiment was tried many years ago in Philadelphia by Swaim, the original panacea man, a vulgar and illiterate fellow who made a fortune by his medicine, the prescription for which he had got from a New York physician for his own use. Swaim built a splendid mansion on Chestnut street and invited the aristocracy of the city to a grand ball on the occasion. But the aristocracy did not come, and Swaim's money failed to open to him the doors of his fashionable neighbors. Brandreth and Jayne among others, made fortunes by deceptive advertising, but they never rose in society above the money mark. An itinerant adventurer once told us that whilst traveling on the Mississippi river and being out of employment, he purchased of an apothecary in a Western city all his old stock of purgative pills and retailed them on the steamboats and elsewhere as Brandreth's pills, with the most surprising results. A single dose often cured, and he could have got all the certificates he might want in favor of Brandreth's pills. The foundation of Jayne's fortune was a chronic diarrhoea, which was cured by a prescription of a doctor in New Jersey. Jayne got the prescription, went to Philadelphia, procured the services of an impecunious and smart young graduate in medicine to write up his lying, and as the cholera was approaching, mounted the flood which leads to fortune by flaming advertisements of "Doctor" Jayne's Carminative. Then came Jayne's Expectant and Jayne's Vermifuge, and so forth, and in a very few years Jayne was able to build one of the costliest edifices in Philadelphia. He became also a celebrated "doctor," though he knew no more of medicine than of Sanscrit when he began his professional career.

Medical Society of the State of Pennsylvania.

The thirty-fifth annual meeting will be held in Philadelphia on Wednesday, Thursday, and Friday, May 14, 15, 16, 1884, commencing on Wednesday, May 14th, at 9 a. m.

Amendment to be acted on, by Dr. H. Leffmann:

No paper shall be read before this Society unless the same shall have been previously read, either in full or in abstract, before a County Society, and by it referred to the State Society.

Appointments for 1884:

To prepare address in Surgery, Dr. John B. Roberts, Philadelphia.

To prepare address in Obstetrics, Dr. Jacob Price, West Chester.

To prepare address in Hygiene, Dr. Benjamin Lee, Philadelphia.

To prepare address in Mental Disorders, Dr. Alice Bennett, Norristown.

To prepare address in Medicine, Dr. W. H. Daly, Pittsburgh.

To prepare address in Ophthalmology, Dr. Wm. S. Little, Philadelphia.

Secretaries of County Medical Societies are earnestly requested to forward at once complete lists of their officers and members, giving the post-office address of each.

Every *delegate*, before admission, shall produce a certificate of delegation, signed by the President or Secretary of his County Society.

Every *permanent member* (not a *delegate*), before admission, shall produce a certificate of good standing in his County Society.—(*Extract from Constitution.*) Wm. B. ATKINSON, M. D.,
Permanent Secretary.

Railroads.—The Pennsylvania Railroad and its branches, and the Philadelphia and Reading Railroad and its branches, will issue excursion tickets at the rate of two cents a mile. All who desire to avail themselves of this should notify the Permanent Secretary, stating the number of excursion orders required, and the railroad over which the party must travel to the place of meeting.

First Aid to the Injured.

One of our funny exchanges gives the following:

1. Bites of all sorts are painful, and if not treated with expedition and skill, they sometimes prove very dangerous. The most common kinds are those received from dogs, mosquitoes and bears. The rarest kinds are trilobites and jacobites.

2. One seldom, if ever, gets a bite when out fishing.

3. If about to be bitten by a dog, while serenading or foraging in a melon patch, immediately take some violent exercise, in order to preserve a good circulation. For instance, run a mile or so without stopping.

4. Never stop running because there is a man with a club apparently chasing the dog—sometimes he is encouraging him.

5. If this does not accelerate the action of the heart, climb the nearest tree.

6. Don't get down again for the purpose of rescuing the sample of your trousers. This is one of the dog's perquisites, and he wants it for his scrap-book.

Paper Towels for Surgical Purposes.

In the surgical dispensary of the Philadelphia Polyclinic, Dr. Roberts has been using, with much satisfaction, Japanese paper handkerchiefs for drying wounds. Sponges are so seldom and with such difficulty perfectly cleansed after being once used, that they are never employed in the clinic. Ordinary cotton or linen towels are much preferable to sponges, which, if dirty, are liable to introduce septic material into wounds. The paper towels, however, answer the same purpose as cotton ones, and are so cheap that they can be thrown away after being used. They cost from \$6 to \$7.50 a thousand. The cost of washing a large number of ordinary towels is thus avoided. The paper towels are scarcely suitable for drying hands, after washing, unless several towels are used at once, because the large amount of moisture on the hands soon saturates a single towel. For removing blood from wounds, a paper towel is crumpled up into a sort of ball, and then used as a sponge. Such balls absorb blood rapidly. The crude ornamental pictures, in color, on the towels, are of no advantage, nor are they, as far as known, any objection.

Pasteur's Enthusiasm.

The French National Society for the encouragement of Agriculture, at its fifth anniversary banquet recently, presented its annual Cup of Honor to M. Pasteur. In returning thanks, M. Pasteur said he was not insensible to praise, but yet praise troubled him, because it belonged to the things of yesterday, and true science always looked forward to new achievements. "There is a great field still to explore," he added. "How many plagues and diseases are there yet to subdue! But have confidence; new methods are discovered, and methods are the soul of science. The great fact evidenced by our meeting here to night is, the alliance between science and practice. You were the first to believe in the triumph of the experimental method. You have enabled me to carry into the domain of fact what formerly would have remained in the region of hypothesis. Your farms have been, so to say, branch establishments to my laboratory. The faith which animated me you have shared, and you have largely contributed to help me to add to the wealth of France, which has abundantly required me."

The Gastroscope.

The *Med. Press and Circular* tell us that Mr. J. Lefter, of Vienna, has constructed a singular modification of the microscope, to which the name of gastroscope has been given. Its use is for exploring the interior of the stomach. It consists of a metal tube, 65 cm. long and 15 mm. thick, bent at an angle of 150° at about one-fourth of its length from the lower end. At the lower extremity is contained an incandescent electric lamp for illumination of the interior of the stomach and an objective, at the back of which is a prism to reflect the pencil along the length of the tube; at the bend it is again reflected by another prism to the eye-piece. Provision is made for a circulation of cold water to prevent the lower end of the tube becoming inconveniently hot.

Physicians as Sanitarians.

A Washington (D. C.) physician had a suit brought against him for \$1,000 damages for failing to take the proper measures for preventing the spread of a contagious disease in the family of the complainant. A contemporary raises the question as to whether it is the function of the physician to prevent disease, and says that if it is, he should certainly be remunerated for such service. With this view, we are entirely in accord. A physician is undoubtedly called upon to do all in his power to stay the progress of contagious disease, but he should also make charges for such services, and be enabled to collect such charges.

Correction.

The inventor of the scrotal compressor described in the *REPORTER* recently, is Dr. G. Miliano, 207 East 13th street, New York, not *Miliaro*, as the types made us say.

—The "Proceedings of the Medical Society of Kings county, N. Y.," has suspended publication after eight years of existence.

OBITUARY NOTICES.

DR. CHARLES L. MARTIN,

Of Allentown, Pa., died November 26, 1883, of cerebral effusion. He was in his sixty-fourth year, and was graduated at the University of Pennsylvania in 1841. The whole of his professional life was passed in Allentown, where he enjoyed an extensive practice.

Items.

—The President has appointed Surgeon Gunnell to succeed Surgeon-General Wales as Surgeon-General and Chief of the Bureau of Medicine and Surgery of the Navy.

—A Spanish medical journal states that there has been born in Madrid an infant with neither arms nor legs. In other respects it is well formed and healthy, and is now five months old.

—A bill has been passed by the New York Legislature appropriating \$50,000 for the enforcement of the act designed to stamp out pleuro-pneumonia and other contagious diseases among the cattle in that State.

—It is reported that owing to the fire which destroyed the establishment of Powers & Weightman, together with large quantities of Peruvian bark, there will be a rise in the price of quinine amounting to about fifty cents.

—By the addition of ten parts of collodion to fifteen of creasote (says the *Revue de Thérap.*) a sort of jelly is obtained which is more convenient to apply to decayed teeth than is creasote in its liquid form.

—The *American Druggist* says that the clinical thermometer was used and commended by Antonius De Haen one hundred and twenty-nine years ago. Its re-introduction occurred fifteen or eighteen years ago.

—The International Otological Congress will be held at Basle, September 1, 2, 3, and 4, 1884. The titles of communications intended to be made to the Congress should be made known to Dr. Burkhardt-Mérion, of Basle, before the 15th of May.

—Under the supervision of Dr. Rush Huidekoper, several specimens are being prepared in the new Veterinary College of the University of Pennsylvania. This work is preparatory to the formal opening of the new department in the early fall.

—Surgeons J. S. Billings and J. S. Brown, U. S. A., have been detailed to attend the International Health Exhibition which meets at South Kensington in May next, and to represent the Department at the International Medical Congress which will convene at Copenhagen in August next.

—It is said that the tooth manufacture of the United States amounts to 10,000,000 teeth per annum. There are twelve manufactories, but one of them, founded in 1864, makes half the number. The value of these teeth is a million dollars. The materials of which they are composed are feldspar, kaolin, and rock crystal.

—The daily press reports 542 suicides for 1883 in Paris, a gain of sixty-three over 1882. The

choice of means of death shows that hanging is not as popular as it is in England, for while only eighty-one hung themselves, 217 used firearms, and 148 drowned themselves. By thirty-seven, the more scientific expedient of burning charcoal in closed rooms was adopted.

—The Meharry Medical Department of the Central Tennessee College, in Nashville, has just graduated eight colored physicians. Thirty-five young negro men had previously been graduated from this school, and it is stated that they have been successful in their work, and have been well received and aided by the resident white physicians.

—The turf surrounding the mansion of Mrs. A. T. Stewart, on Fifth Avenue, New York, is said to have been taken from the grounds of the old New York Hospital, at Broadway and Pearl street, and to be about one hundred years old. When the hospital buildings were torn down some years ago, Mr. Stewart purchased the sod from the Governors, and had it relaid about his new house, which was then in course of erection.

—According to Dr. Sach, of Buenos Ayres, in the *Popular Science Monthly*, there is no danger of an exhaustion of the quinine supply. The experimental plantation in Java and the Island of Reunion have been very successful, and besides these nurseries, the trees have been cultivated in Bolivia by the million for ten years. At three places in the last-named country, taken as they come, the number of trees growing is given severally at 70,000, 20,000, and 3,500,000.

QUERIES AND REPLIES.

EDS. MED. AND SURG. REP.—

In reply to "Medica" in your issue of the 23d ult., I would say to his first query that his patient has a "lacerated cervix," which can be remedied by an operation. Then cease giving the so-called "emmenagogues" and "tonics" for awhile, and put her upon some good emulsion of cod liver oil, say Phillips' palatable emulsion, as a restorative.

To his second query: Use astringent suppositories.

R. L. M.

Anæsthetics in Labor.

EDS. MED. AND SURG. REP.—

I shall be greatly indebted to you for any information you may be pleased to give me on the following points in relation to *anæsthetics in labor*:

1. What is the best anæsthetic for such cases?
2. What is the effect of chloral hydrate administered previous to the anæsthetic?
3. Do you find that it arrests the uterine contractions so as to retard delivery?
4. What effect, if any, does it have on the child, either before or after delivery?
5. Does it have any tendency towards the production of post-partum hemorrhage?

Any other information of interest not covered by these queries will be gladly received.

To those sending replies, I shall be pleased to send a reprint of the report on this topic.

W. E. ZIEGENFUSS, M. D.

Albany, Wisconsin, February 29, 1884.

Dr. V. G., of Mexico, wishes suggestions in a case of hypochondria in a man of middle age, without obvious lesion.

THE MEDICAL AND SURGICAL REPORTER.

ORIGINAL DEPARTMENT.

LECTURE.

THE CIRCULATION IN THE NEWLY-BORN.

BY W. S. FORBES, M. D.,

Demonstrator of Anatomy, Jefferson Medical College.

GENTLEMEN: In the new-born child, at full term, the blood is not *drawn* into the pulmonary arterial branches and into the lungs by the expansion of the lungs, as is generally believed and taught; on the contrary, it is *forced* into and through the pulmonary artery, and its right and left branches, and into the lungs, by the contraction of the right ventricle, and by the elasticity of the walls of the pulmonary arteries; while at the same moment it is prevented from going through the ductus arteriosus and into the aorta by a procedure that I now wish to point out and demonstrate to you.

In the very young *fœtus* the thorax and abdomen form one cavity, as in birds, reptiles, and fishes. The diaphragm in the *fœtus* is developed by a process of growth from the circumference to the centre, and when developed is in a passive state until birth. In the new-born child, at full term, the muscular diaphragm is called into immediate action, and in contracting performs at once a most important function in compressing the ductus arteriosus, thereby diverting the current of blood into the two branches of the pulmonary artery, which go respectively to the right and left lung. The peculiarities in the arterial system of the *fœtus* are the communication between the internal iliac arteries and the placenta by means of the umbilical arteries, and the communication between the pulmonary artery and descend-

ing part of the arch of the aorta by means of the ductus arteriosus. In the *fœtus* and up to birth, at full term, the long axis of the heart is more nearly vertical than in the adult, and the right and left branches of the pulmonary artery are, relative to the main pulmonary artery, very small, and come off from the posterior aspect of the artery, while the ductus arteriosus at this period is much larger, and is in front of the branches and nearer the sternum, and is in fact the continuation of the main pulmonary artery to the arch of the aorta, into which it opens just below the origin of the left subclavian artery, and so conducts the current of blood from the right ventricle into the arch of the aorta.

In order to show you the way in which the contraction of the muscular part of the diaphragm closes the ductus arteriosus by causing pressure upon it, I shall have to demonstrate to you the pericardium, through the fibrous wall of which sac the ductus arteriosus runs to reach the arch of the aorta.

The pericardium is a conical fibro-serous sac, in which the heart and the first part of the great blood-vessels are contained. The inner serous portion of this sac invests the outer surface of the heart everywhere, and is reflected from the heart to the inner surface of the outer fibrous portion of the sac. The base of this conical fibro-serous or pericardial sac is attached to the upper surface of the broad aponeurotic central tendon of the diaphragm. At the upper part, or towards the apex of the cone, the fibrous portion of the sac has a number of openings in it for the lodgment of the great blood-vessels which go to and come from the heart. Now this fibrous pericardial sac is composed of the same tissue as that which we find

composing the outer membrane or sheath of the great blood-vessels; and it is lost upon or continuous with the fibrous sheath of these great vessels, the largest of which is the aorta. The great vessels issuing from and going to the heart are supported in their relative positions while going through the fibrous pericardial sac, which at the same time forms tubular prolongations upon them. On the posterior aspect of the fibrous pericardial sac oblique and transverse fibrous bands are found, thus strengthening the sac and making a sort of fibrous scaffolding for the support and protection of the great cardiac vessels and the heart itself.

From the superior right and left external lateral surfaces of this pericardial sac, prolongations of the fibrous tissue continue upwards as strong bands to the inner margin of the first rib on each side of the thoracic cone, and then coalesce with the thoracic fascia described by Sir Astley Cooper in his little work on the Anatomy of the Thymus Gland. Sir Astley says: "The thoracic fascia performs three important offices: 1. It forms the upper boundary of the chest, as the diaphragm does the lower. 2. It steadily preserves the relative situations of the parts which enter and quit the thoracic opening. 3. It attaches and supports the heart in its situation through the medium of its connection with the aorta and larger vessels which are placed at its curvature." Now this thoracic fascia of Cooper is supported above by the deep cervical fascia, which is strongly attached to the transverse processes of the cervical vertebrae and to the stylo-maxillary ligament on each side of the base of the skull. We find, therefore, on each side of the body of man a continuous fibrous plane, inelastic and inextensible, reaching from the base of the skull and the upper part of the vertebral column, and extending to the cordiform appendage or central tendon of the diaphragm.

These two lateral planes thus reaching from the diaphragm to the upper part of vertebral column and to the base of the skull are, as it were, two superior crura of the diaphragm which *prevent the descent* of its central tendon when the muscular part of the diaphragm contracts in respiration.

Indeed, if the central tendon of the diaphragm, with its attachment to the base of the fibrous pericardial cone, were to descend, or if any part of the two extensive fibrous planes I have pointed out to you were to give way, what a pernicious effect such an accident would have upon the heart and great cardiac vessels! The fact is, the

entrance and the exit of the cardiac vessels through the openings of the fibrous pericardial sac hold a fixed and unvarying relation to the vertebral column. Thus the ascending vena cava enters the fibrous pericardium through the highest part of the central tendon of the diaphragm at the lower anterior aspect of the right side of the ninth dorsal vertebra; it here goes through a tendinous quadrangular opening, but receives no covering from the fibrous margin.

The descending vena cava enters the fibrous pericardium at the anterior aspect of the lower part of the right side of the fifth dorsal vertebra, and receives a fibrous prolongation from the pericardium. These openings into the fibrous pericardial sac of the two venæ cavæ do not change, nor does their relation to the vertebral column vary; they are fixed. I must remind you just here that the three layers of lumbar fascia, sheathing the quadratus lumborum and erector-spinae muscles of each side, and attached to the spines of the sacral and lumbar vertebrae and to the crest of the ilium, and to the lower border of the twelfth rib, perform the same function in keeping the lateral aspects of the base of the thoracic cone from being drawn upwards by the attachments of the muscular diaphragm, that the lateral fibrous planes or the superior crura of the diaphragm which I have demonstrated to you as being attached to the processes of the cervical vertebra and through the base of the skull, do in keeping that part of the central tendon of the diaphragm embraced by pericardium from being drawn downwards. The quadratus lumborum muscle reaching from the crest of the ilium to the twelfth rib, assists to hold, as it were, the base of the thoracic cone, while the lateral muscular planes of the diaphragm reach from this twelfth rib and the ligamentum arcuatum extend to the lateral aspect of the base of the precordial cone and thus make it tense.

We have the liver, which weighs four pounds avoirdupois, suspended from the dome of the diaphragm by means of the suspensory or falciform ligament, just beneath the right fibrous plane, which is vertical in its direction from its attachment to the cervical portion of the vertebral column and the base of the skull. This four-pound liver, the largest gland in the human body, is then really suspended from the cervical portion of the vertebral column, and from the base of the skull through the deep cervical fascia and the stylo-maxillary ligament. Along the sides of the two fibrous planes I have pointed out, we have the great cervical blood vessels lodged, as upon a

scaffolding, and in the thorax the phrenic nerves descending upon it to reach the diaphragm.

The ductus arteriosus is lodged in an elliptical opening in the fibrous scaffolding beneath the arch of the aorta. It escapes through this opening to reach the descending portion of the arch of the aorta, which is outside of the fibrous pericardial sac. This elliptical opening for the lodgment of the ductus arteriosus in its long axis extends obliquely from above, downward and forward, and to the left, going in front of the descending aorta, and above the left branch of the pulmonary artery. The tendinous fibres forming the margins of this elliptical opening embrace the ductus arteriosus, and are connected to its external coat by connective tissue.

The muscular fibres of the diaphragm contracting at the first inspiration at birth, bring together the margins of the elliptical opening in the fibrous scaffolding, and thus compress the ductus arteriosus, and eventually close it—thus changing the current of the blood from the ductus arteriosus into the right and left branches of the pulmonary artery. Especially is this compression made by the contraction of those muscular fibres of the diaphragm which ascend upon and are attached to the anterior left aspect of the pericardium, and which are so easily observed in the young child.

The alternate pressure and relaxation made on the ductus arteriosus by the contracting diaphragm, is exactly similar to the procedure we now adopt in closing by pressure the main artery in cases of aneurismal tumors, and the effect in both instances is exactly the same. When the ductus arteriosus is being compressed by the contraction of the muscular diaphragm, the right and left branches of the pulmonary artery going to the lungs are being distended and permanently enlarged until their united capacity is equal to the entire volume of blood in the main pulmonary stem, and thus the collateral circulation is eventually established with the aorta by means of the appropriate organs (the blood going through the ramifications of the pulmonary arteries, through the pulmonary capillary into the pulmonary veins, and to the left auricle, and thence into the left ventricle, and thence into the aorta). The walls of the ductus arteriosus in the meantime, being compressed, coalesce and become permanently closed. In some cases the ductus arteriosus is entirely removed by the pressure, so that not even a vestige of the fibrous cord is to be found. The contraction of the muscular diaphragm not only in this way closes the ductus arteriosus, but at the same moment holds open

the gateway, as it were, of every vessel going into and out of the fibrous pericardium. For if one stands or sits erect and straightens the vertebral column, and at the same time contracts his diaphragm, taking a long breath, he feels more comfortable, because these gateways are thus held open and the blood goes to and comes from the heart with greater facility than if they were not held open, as they are not held well open when one sits in a stooping or doubled-up posture. By instinct, as it were, we straighten ourselves when we wish to breathe easier. In the anatomist's eye, it is because the gateways of the heart are held open and tense, and the blood goes into and comes out of the heart and great arteries with greater facility, and the sides of the pericardium being drawn tight by the contracting muscular diaphragm, the heart itself is protected from lateral pressure between the expanding lungs.

The lateral muscular portions of the diaphragm in contracting usually descend, and thus the vertical diameter of the thorax on each side is extended. But they may not be permitted to descend by the stronger abdominal muscles contracting, or by tight lacing, as in the case of some women of fashion; nevertheless the muscular diaphragm, though it may not be permitted to descend, contracts on its own plane, and makes tense its *superior crura* and the *fibrous scaffolding*, and thus exerts its influence in holding open the gateways of the cardiac vessels and in protecting the heart itself from lateral-lung pressure, and thereby promotes the circulation of the blood and protects the central organ of the sanguiferous system.

The descent of the lateral portions of the diaphragm is not necessary to respiration; this is manifest from ordinary observation; but the contraction of the muscular diaphragm, though it may not be permitted to descend, is necessary in order to protect the heart from the movement of surrounding viscera, and in order to promote the free circulation of the blood through the vessels forming the cardiac roots. This statement is verified in the clinical histories of injuries of the phrenic nerve and of the diaphragm.

If one side of the muscular diaphragm does not contract on account of paralysis of the phrenic nerve of that side, then that side of the fibrous pericardial plane is not held tight; it is in a relaxed state, and the lung on that side expanding presses it against the heart.

In bilateral paralysis of the diaphragm, the heart is pushed backwards by the lungs advancing in front, while at the same time it is com-

pressed on each side: the heart's action then is always labored.

The anterior and lateral attachments of the diaphragm to the base of the thoracic cone cause the epigastrium and right and left hypochondriac region, in cases of bilateral paralysis, to become depressed. Duchene informs us that if in these cases the phrenic nerves be galvanized, the diaphragm acts again with proper strength, and during inspiration the thoracic and abdominal walls rise simultaneously, and then there is no longer a depression in the epigastrium and hypochondriac regions.

If we examine the natural history of the diaphragm, we observe that it is first found in mammals. These animals require a diaphragm to protect the central organ of circulation from the encroachment of the neighboring lungs and abdominal viscera, and by its contraction act in protecting as well as promoting the function of the heart.

In birds, and in turtles and tortoises, such an organ as the diaphragm is not required. In these animals the thoracic and abdominal viscera are in one and the same cavity, but the movement of the lungs is limited by means of pleural attachments, and the heart and its great vessels are protected by peritoneal folds which form restrictions by being attached to distant points of a rather fixed bony frame-work. In these animals the diaphragm is not found, as it is not needed.

To sum up, then, I have endeavored to demonstrate to you that—

1. That portion of the central tendon of the diaphragm embraced by the base of the pericardium is prevented from descending in inspiration by the *superior tendinous crura* of the diaphragm, which are formed by the lateral parts of the fibrous pericardium reaching on each side to be attached to the first rib and through the deep cervical fascia to the transverse processes of the cervical vertebrae, and through the stylo-maxillary ligament of either side to the base of the skull.

2. These superior tendinous crura of the diaphragm are connected together inferiorly by transverse and oblique fibrous bands, thus forming a fibrous scaffolding for the support and protection of the heart and the great cardiac vessels.

3. The opening in the fibrous scaffolding for the lodgment of the ductus arteriosus in foetal life is closed at birth by the contraction of the muscular diaphragm, and especially by those muscular fibres ascending on the fibrous pericardium from the anterior left side of the diaphragm, which muscular fibres are well developed in the newborn child.

4. That the blood at birth is *forced* into and thorough the pulmonary artery and its right and left branches and into the lungs by the contraction of the right ventricle of the heart, which at this moment has its walls as thick as those of the left ventricle, and by the elasticity of the pulmonary artery, and is not *drawn* into the pulmonary arterial branches and into the lungs by the expansion of the lungs, as has been heretofore taught.

5. The superior fibrous crura and the fibrous scaffolding between them are made tense, and their openings made patulous for the lodgment and the protection of the heart and its great vessels, and for the promotion of the circulation of the blood through them by the contraction of the muscular diaphragm.

6. The opening of the inferior vena cava, the highest point in the central tendon of the human diaphragm, holds a constant and fixed relation to the right anterior inferior border of the ninth dorsal vertebra.

7. That in the contraction of the muscular sides of the diaphragm they may be prevented from descending by the contraction of the stronger abdominal muscles acting upon the abdominal viscera. Though not permitted to descend in contracting, the muscular diaphragm still makes tense the crura.

8. The diaphragm, we may believe from its clinical as well as from its natural history, is rather an appendage to the circulatory apparatus, and not "essentially the chief agent in respiration," however much it may assist in performing that function.

COMMUNICATIONS.

LEGAL REFORM DEMANDED IN THE TREATMENT OF INEBRIATES.

BY T. O. CROTHERS, M. D.,

Superintendent Walnut Lodge, Hartford, Conn.

The following case is by no means uncommon, and points out a positive wrong, and source of danger that must be met and remedied by the teaching of physicians.

The general wholesale way in which persons arrested for intoxication are fined and imprisoned, carries conviction that this is not the true remedy, the application of which is only governed by the number of the offense.

In reality, the better judgment of courts and prison authorities condemn this means, and only

carry it out from a necessity which has no other resource.

By a strange combination of events, the penal code concerning inebriates has not changed for over two thousand years.

The teaching of the old Grecian law-giver that drunkenness could best be prevented by punishment, has been so persistently urged by moralists that it has survived all civilization and progress, and appears in modern courts of justice, a literal relic of the dark ages.

Any inquiry of prison authorities will reveal the fact that large numbers of inebriates are repeatedly being returned to prison for the same offense over and over again, growing steadily worse. Also, that a short term of imprisonment at first really destroys them, and makes recovery almost impossible, and is followed by repeated sentences for the same cause. Ninety-nine per cent. of all persons who come to jail for inebriety the first time are returned, and become incurables dating from that event.

These facts are accessible and can be proved by the records of courts and prisons all over the land.

Yet every effort to legislate on a higher plane of justice and humanity, is resisted by theological dogmas of the nature and character of inebriety.

The fear of taking away personal responsibility, and thus encouraging inebriety, by calling it a disease, has kept alive this theory of punishment with the most disastrous results to the victim.

A noted judge remarked, as long as society supports such views, the inebriate can never recover, but will be always destroyed by this means to help him.

The case which I shall present for study to support these views came into possession of a large property late in life, and the question arose as to his mental capacity to care for and will this property to others.

A very careful study was made of his past history, which was placed in my hands for a decision.

Most of the leading facts were fully confirmed by other evidence, so its accuracy was unquestioned.

H— was born and reared on a farm. His father was temperate; his mother was inclined to melancholy, and died soon after his birth of consumption.

He grew up to fifteen years without any peculiarity, except great sensitiveness to slights, and a morbid fear that he would not be considered equal to others of the same social standing.

After he passed puberty he became very proud and egotistical, and resented with violence any opposition. After an attack of anger he would be prostrated, and lie in bed a day or more.

At seventeen years of age he was violently opposed in a love match, and seemed to have suffered from a shock to his nervous system, which lasted over a year, manifest in a changed disposition and low state of health, which caused him to remain in bed from one to four days at a time. He joined a church, and became an active temperance worker, although he had not used spirits at this time.

At twenty he left the farm, having a fair academic education, and entered a manufactory. He was at this time temperate, and in good health. Five years later he married, and was in good circumstances; the only feature of his character was great pride, and scorn of low ways of living and manners.

At thirty-one years his wife died, and the firm failed, throwing him out of employment; and soon after, he began to drink to intoxication. Distinct periods of low spirits and depression came on, which always ended in a paroxysm of drinking. When this was over, he seemed more proud-spirited than ever, and more determined to win the respect of others.

At about this time he invented a machine which proved a source of wealth, and placed him in easy circumstances. From this time no event of note took place, except an irregular paroxysm of drink from two to four times a year, until he had reached forty, when one day, while drinking, he committed an aggravated assault on a stranger, and was arrested. He denied all knowledge of the event, but the court fined him heavily. The publicity of this distressed him, and he claimed to be sick for some weeks after.

Soon after, while drinking, he became violent, destroyed much property in the saloon where he procured his liquor. He was arrested and fined. From this time each drinking paroxysm was marked by some violence to persons or property, for which he was arrested, and at last sent to jail.

After this first imprisonment a total change of character took place. He was reckless, bold, and sought the lowest company; boastful, quarrelsome, drank constantly, lost personal pride, had no ambition for anything except to drink and play cards. He lost his property, and became a bar-keeper and low gambler, and was sent to jail for drunkenness and assault eighteen times in eleven years. He then became involved in a bank robbery and was kept in prison for two years.

After this he was so violent after drinking as to be considered insane, and was sent to an insane asylum. He was discharged as a drunkard, and not insane.

For the next seven years, up to the time he came under my observation, he had led a roving life as a tramp, spending all his time in station-houses, almshouses, and on the road traveling.

The same violence marked his periods of excessive drinking, only less vindictive. He was feeble in mind and body, had delusions of strength to stop at will, attributed all his misfortunes to a plot of some enemies. Was very religious at times, and full of hope; then would display a degree of petty meanness, indicating the lowest motives. He would steal at times, and show much cunning to conceal it.

Physically, he was anæmic, had cirrhotic liver and fatty heart, had a trembling, uncertain gait, complained of pain in his head and tender spots along the spine. His memory had failed. He affirmed that he could never recollect after drinking a certain amount of spirits. He gave up the use of all strong liquors except beer and bitters, and insisted that he had reformed.

The question was on his mental capacity to care for, and dispose of property. He had been living quietly and regularly in a good home when I was called, and was greatly improved in general health. Two physicians had given an opinion that he was fully sane, and capable of managing his property.

To this I totally dissented, for the following reasons:

1. He had evidently inherited a degenerate nervous organization, which developed into inebriety from the mental shock at the loss of his wife.

2. This was further strengthened by the destructive or violent delirium which accompanied each attack of drinking.

3. The repeated imprisonment for these offences increased the mental degeneration, still farther developing all the conditions of chronic inebriety, and soon in a total change of character and habits of living.

4. The integrity of the brain was permanently impaired by the various circumstances of life. His delusions of strength to stop at will, and of persecution, as well as religious paroxysms and other minor phases, was evidence of this.

The history of a trance state, in his loss of memory at these violent periods, was also distinct in his senseless assaults and unusual acts.

My opinion was not adopted, and in two months

after coming into possession of his property, he opened a grand saloon in an obscure country village, and imported a large amount of choice wine.

After drinking to intoxication, he destroyed most of the gilded fixtures, seemingly as a matter of pleasure. Finally, his property was put in the hands of trustees, and incipient paralysis has already appeared.

This case was largely the result of dangerous penal methods of treatment. His first imprisonment increased the very disorder it was designed to relieve. He was made more hopeless and incapable of rising above his diseased impulses, by the prison treatment. The state actually educated and forced him into the lowest stage of degeneration.

Pecuniarily the problem is a startling one. It cost the tax-payers to take care of him in jail not less than three thousand dollars, with no result but to make him worse.

Had his malady been fully recognized at first, and he been committed to a workhouse hospital for this class, recovery would have most naturally followed. In such a place the mind and body would have been built up, and he would have been fitted to take place as a producer in society, and not unfitted and made more incompetent to go back into healthy society and living. Hundreds of cases are thrown into prison on the general principle that the shame of this punishment and the suffering which comes from it will deter them from drinking again, the result of which is to crush out the very element upon which recovery depends. All that the prison can do for the inebriate is to remove him from alcohol; what it fails to do, is to build up the weakened brain and nervous system. Prison diet and hygienic surroundings can never restore the weakened organism. The psychical influence of prisons leave an impress that can never be estimated.

The bad associations, the wounded pride and ambition, and the crushing out of that unknown element which gives tone and vigor to the organism, and sustains it in the hour of peril, are all factors whose effects can be fully realized.

A great reform is demanded in the penal treatment of inebriates, and the public look to the medical profession for help and guidance.

To send all cases to jail is obviously as great an error as it would be to amputate all cases of fracture of the lower extremities.

These cases must come under medical care and study, and should be quarantined in hospitals by themselves, and special appliances hunted out for each one.

It is a scientific problem, as well as social and pecuniary, and its solution is demanded from all sides.

The facts upon which it rests are within the range of every medical man, and the time has come for change and reform.

THE UNKNOWN FACTOR IN THE EQUATION OF THE NERVOUS SYSTEM.

BY J. M^YF. GASTON, M. D.,
Atlanta, Georgia.

The Action of Medicine on the Cure of Diseases.

This is a question of different import from that of the action of medicines in the cure of diseases, which implies an investigation of the rationale of medication, and its proper effect upon the disorders of the organism; and thus being in its character essentially physiological and pathological, it is not directly involved in the results of clinical observation. The aim and end of the proposition which is here submitted for consideration, is understood to be a systematic analysis of the facts which are developed in connection with the influence of medicinal agents upon the human system.

If the most enlarged scope of inquiry be allowed in this field, the question may be opened as respects the salutary result from the resort to medication in any case, and the propriety of abstaining from the use of medicine.

As this point should be put at rest before proceeding any further with the definition of our subject, it may be proper to set aside all skepticism in regard to the sum total of good or evil that results from the indiscriminate or even injudicious employment of medicine, and eliminate all guessing from the proofs of medicinal effects upon the system.

While it is well-established by recent statistical records, that many acute diseases run their course favorably without medication, and that we may reasonably depend upon the *vis medicatrix nature* in some cases, yet the salutary influence of medicine upon the majority of diseases is clearly demonstrated by the practical results in the daily experience of physicians. There may be instances of sickness for which medicine is not indicated, but our concern is about those cases for which it is requisite; and the object of our inquiry respecting "the action of medicine on the cure of diseases," is to determine the mode in which it may be employed to the best advantage. "Medicine is any substance, liquid or solid, that has the property of curing or mitigating disease," and

our investigation pertains to the most efficacious means of cure. It is no part of my undertaking to solve the intricate problem of the quality of the various medicinal agents, nor to decide upon the relative effects of the different classes of remedies. Accepting the great cardinal distinction of drugs, according to their special influence upon the animal economy, I propose to delineate from the observations made by others, and from my personal experience, the characteristic effects of medication upon the human organization.

The influence of subcutaneous and other medicated injections upon the vital functions, illustrates strikingly "the action of medicine on the cure of diseases," and I trust that this phase of medicinal influence may be recognized as being completely within the sphere of inquiry submitted in this proposition.

As the nutriment of the body is introduced through the stomach, it might be naturally inferred that the general system should be also medicated by the same channel. The fact, however, must be taken into consideration, that the food undergoes various changes in the process of digestion and assimilation, which are not requisite for the effects of medicine upon the organism. The influence of most medicinal agents is to some extent impaired by the action of the gastric juice, and by admixture with the alimentary substances in the stomach. In view of this complication, a direct route to the sanguiferous and nervous systems, by the immediate absorption of medicine, has been found more certain in manifesting its appropriate therapeutic effect. This is seen in the *immediate influence of the medicine upon the nerve fibres* when injected into the areolar or cellular tissue.

The circuitous route through the entire system of veins and arteries, is not at least requisite to produce the effect of those medicinal agents directed especially to the nervous development.

Facts do not sustain the doctrine inculcated by Headland, that medicinal agents must enter the circulation and take the rounds of the blood, before their effects can be exhibited upon the animal economy. I appeal to all who have witnessed the almost instantaneous influence of anodyne injections into the areolar tissue, to correct this view of the action of medicines, when used by the hypodermic process, or when injected into serous or mucous cavities. Being impressed with the insufficiency of the experiments, and the faultiness of the reasoning, by which his proposition is claimed to be sustained, I have to draw attention to a few points that show this weakness.

The inference drawn from the experiment that it takes only 65.76 seconds for any substance to pass round the entire circulation, and that hence all medicinal agents may reach the nerve-centres within this period through the blood, does not follow as a necessary consequence; since the appropriation of the active principle of the medicine demands other conditions that are not complied with in the given cases, and there is a more rational and satisfactory explanation.

Neither does the experimental proof, afforded by division of all the nerves of a part, without impeding the circulation of the blood, avail anything; as the blood reaches the nerve-centres, and this eventually produces the effect of the medicine upon the nervous system. The case adduced of the continuity of a nerve, without the supply of blood, proves nothing; as the life of the nerve ceases with the obstruction of its necessary nourishment by the circulation, and therefore the contact of any medicinal agent with a dead nerve cannot give any result. Another fallacy consists in claiming for such cases as manifest influence through the nerves, that the proper action is on the centre, and that the nerve-centre produces the effect, and not the agent. This is simply absurd, and does not demand serious refutation.

I presume that all are of the opinion that the nerve-centres are essential to the propagation of any impression through the nervous system; yet it is none the less true that such impression is received through a nervous connection, and *that this impression depends upon the intimate relation of the minute nerve-fibrils to the capillary blood-vessels, upon which the primary impression is made by the absorption of the active agent.*

There is no doubt in regard to the general principle, that medicinal agents enter the general circulation, and produce their effects upon the different secretory organs by actual contact with their texture. Yet, granting this proposition in its widest acceptation, we have numerous instances that are not to be accounted for by such a long circuit in the development of the effect. If it can be demonstrated in any instance, that an influence operates upon the vital organs from peripheral impressions, without absorption into the general circulation, it is evident that such results from the contact of medicinal agents may be uniformly anticipated.

All the class of revulsive, including the sudden action of extreme heat and cold upon circumscribed portions of the cutaneous surface, are held to be exceptional cases; and their influence must be explained upon the reflex principle of

the nervous system. Yet, if such impressions are extended without any shadow of claim that absorption has anything to do with the effect, then it is fair to infer that the first influence of an agent may be manifested directly upon the minute fibres of the nerves, and that the influence may be propagated thence to the nerve-centre, and extended through this to the entire organization. Note, for example, the effect of strong hartshorn when confined in contact with the skin, where no absorption can occur through the unbroken cuticle; and yet its energy is seen and felt like that of boiling water upon the surface. It is not merely a mechanical influence, nor yet chemical, but clearly vital, and must depend upon the rapid extension of the primary impression, through the nerves to the nerve-centre, which is returned with energy to the tissues of the surface, and with a special modifying power to the entire organization. By no other link of association can this result be explained, than through the reciprocal action and reaction of the different elements of the nervous system. While it is clear that the circulation of the blood in the capillaries is a prerequisite to any manifestation of nervous power, no causative influence can be attributed to its passage through the veins and arteries from and to the surface upon which the impression is made by the agent.

If then the contact of any substance with the superficial nerve fibres produces an impression that may be transmitted to the internal organs, and which by a reactionary power of the nerve-centres is extended throughout the system, we are prepared to appreciate the mode in which the subcutaneous impressions of medicines upon the capillaries affect the minute nerve-fibres primarily, and are extended consequently to the general system.

From an early period in medical history, isolated facts have been presented to illustrate the rapid influence of agents introduced beneath the skin; and more recently medicinal substances were inserted under the cuticle with a view to secure certain local or general effects, but without any correct appreciation of the principle upon which hypodermic applications have since been used so successfully.

While others had previously resorted to one or another form of medication through the skin, it was only in the year 1854 that Dr. Alexander Wood, of Edinburgh, initiated the method of subcutaneous injections for the relief of pain and the cure of diseases. The discovery of the vasomotor system of nerves by Dr. Brown-Sequard, a

few years previously, gave a plausible clue to the efficacy of this method of treatment; yet for a considerable time it did not receive a large share of consideration from theorists, nor was it adopted very generally by practitioners until within the past fifteen years. At the outset, the use of the hypodermic syringe was limited to a certain class of cases in which pain was the predominant element; but latterly it has been employed for the introduction of a variety of medicated solutions; and the observation of its advantages has led to its use in an extended field of diseases. It has been ascertained that in the application of means for the relief of physical disorders, we may operate from without inward in many cases, with a prospect of securing better results than can be anticipated by directing our remedies from within outward. This is the case, especially, when our measures are addressed to the peripheral distribution of the nerves. The centripetal influence of the medication being first effected, there ensues promptly a centrifugal development of the effect, which extends to all parts of the body.

(To be continued.)

HOSPITAL REPORTS.

A CLINICAL LECTURE DELIVERED AT THE UNIVERSITY OF PENNSYLVANIA.

BY D. HAYES AGNEW, M. D., LL. D.,

Professor of Surgery and Clinical Surgery in the University of Pennsylvania.

Reported by WILLIAM H. MORRISON, M. D.

Vesical Calculus—Crushing by Bigelow's Operation.

GENTLEMEN: The first case which I shall show you is one of stone in the bladder, and while the patient is being etherized, I shall make a few remarks in reference to this subject.

Stone in the bladder is distributed universally over the globe. I do not know that there is any locality in which it is not encountered, but there are some regions in which it is more common than in others. In the New England States, and in North and South Carolina, Illinois, Texas and Louisiana, it is rather an uncommon affection; but in Kentucky, Ohio, Tennessee, Alabama, and Missouri, it is frequently met with. When we cross into continental and other countries, the same difference is found. Stone in the bladder is more common in the southern part of France than it is in the northern part. In England, a large proportion of the cases of this disease is found in the counties of Norfolk and Suffolk; and in the northern counties of Ireland and Scotland stone is more common than in the southern parts of the same countries. Its unusual prevalence in some of these districts is attributed to the fact that the people drink a great deal of cider. Whether or not this exerts any influence, I think is questionable. In India, it is

in the northern part that the greater number of cases occur. In China, the greater number of cases are found within a radius of forty or fifty miles around Canton. The prolific cause of vesical calculus is generally due to some defect in the organs of digestion and assimilation.

Stone may form in two different parts of the body, either in the kidney or in the bladder. Stones composed of uric acid or oxalate of lime, usually commence in the kidney. In consequence of the aggregation of a few crystals of one or other of these compounds, a concretion is formed in the infundibulum. This passes into the pelvis of the kidney, and thence into the ureter. Its size is perhaps disproportionate to the calibre of the ureter, so that it becomes arrested and is detained in its passage toward the bladder. This gives rise to an attack of renal colic. After a time, the pressure of the stream of water behind, and the gradual yielding of the muscular coat of the ureter, allow the stone to pass until it slips into the bladder, and the pain suddenly ceases. Fortunately, in many cases, the concretion is discharged after entering the bladder, and this is the end of all trouble. Sometimes other attacks may follow, but often there is but one attack, and the patient is permanently relieved. If, perchance, in consequence of its catching in some of the folds of the bladder, or if the bladder is somewhat sacculated, or has a deep *bas-fond* resulting from prostatic trouble, it does not immediately pass out, it gradually grows by deposit, until it forms a large mass which we call a vesical calculus.

When stone begins in the bladder it is usually of the phosphatic variety, and generally results from some disease of the lining membrane, or from prostatic obstruction. Under such circumstances products are formed which, acting on the urine, cause a deposition of its salts and the formation of deposits, which gradually grow until they become large enough to give rise to symptoms. Sometimes a stone is due to obstruction of the urethra. A stricture, especially in old persons, predisposes to the formation of stone, simply because the urine is not completely evacuated from the bladder, and the residual urine serves to produce a deposit, which may become the nucleus of a stone.

Stones which form in the kidney usually have a laminated character, and with a nucleus in the centre. It does not follow, because a stone begins as an uric acid or oxalate of lime calculus, that the whole stone will be made up of these compounds. Instead of this, there may be different strata, one layer being composed of uric acid, another of oxalate of lime, and another of phosphates. The character of the stone depends upon the chemical composition of the urine. Phosphatic stones are often only a conglomerate like dry mortar, rendered adherent by tenacious mucus.

In reference to the symptoms, the first thing noticed by this patient was the desire to pass water more frequently than had been his custom, compelling him to rise during the night two or three times. This frequency continued to increase until he was obliged to pass urine almost every hour. In addition to this, the dislodgment of the urine from the bladder was accompanied with pain which he locates at a certain point. It is not in

the bladder, but at the end of the urethra. The pain is not felt before or during the passage of the urine, but just at the termination of the act. This pain on urination is a very important point in diagnosis. It is suggestive of stone in the bladder, because we find under such circumstances (not always, but very generally), pain of this character. Pain is felt at the completion of the act of urination, because when the bladder is empty, the sensitive walls of the organ contract on the irregular surface of the stone, causing pain. It is felt at the end of the penis, because we always refer irritation of a nerve to the peripheral distribution of the nerve, and not to the point where the irritant acts. In addition to pains and frequent urination, the water contains mucus, pus and some blood, the stream being often suddenly interrupted by the concretion rolling into the neck of the bladder.

The treatment of these concretions may be divided into the medical and the surgical. The medical treatment is simply palliative. At one time the profession were largely engaged in experiments looking to the solution of stones. These have signally failed. There is, however, no doubt that in the case of stones composed of phosphates or urates, the irregular surfaces may be smoothed off and the calculi rendered less irritating by the use of alkalies, as bicarbonate of sodium. Some of the German waters have from this circumstance obtained considerable popularity in alleviating the sufferings from stone.

The only way to cure stone in the bladder, is to remove it. There are two ways of accomplishing this result. One is to introduce an instrument, grasp the stone, and crush it; the other is by the cutting operation, the incision being made either through the perineum, or above the pubes, called the high or supra-pubic operation. The crushing process is done with an instrument called a lithotrite, which was devised a long time ago, in a rude form, by Gruithuisen, a Bavarian surgeon, but which was much improved by Civiale, and particularly by Mr. Weiss, of London, and by Sir Henry Thompson. It consists of two blades, a male and a female blade. The instrument is passed into the bladder, the blades separated, and the stone caught. Then, by means of a screw, the stone is crushed. The smaller fragments are next picked up and crushed, until the stone is reduced into particles so small as to readily pass through the urethra. The old plan was to break the stone and allow the patient to pass the fragments through the urethra. Under these circumstances a fragment would often become entangled in the bladder or urethra, giving rise to a great deal of pain, and frequently leading to the formation of another stone.

The operation which has of late very largely filled the mind of the profession, is that which is known as the Bigelow operation, or litholopaxy. This consists in crushing the stone at one sitting, into fragments so small that they may be removed with an evacuator. The evacuator is not a novelty, for it is by no means a new instrument. The novelty consists in the prolonged operation, the crushing being continued until the stone is broken into sufficiently small fragments, even if this should require an hour or longer, and in the improved character of the evacuator. The opera-

tion is still on trial. So far, it is viewed with favor by the profession. I have performed it a number of times, and am pleased with the results, but I am not yet prepared to say how it will compare with other operations, at least until a sufficient number of cases have been recorded to make a comparison valuable.

What I propose to do to-day is to introduce this lithotrite, catch the stone, and if it is soft enough and not too large, crush it and remove the fragments with this evacuator, which consists of a gum bag which is filled with tepid water. At the bottom is a glass receiver into which the sediment drops. The bag has also a nozzle which connects with a large catheter, after the latter has been introduced into the bladder. The bulb being compressed, the water is forced into the bladder, and when the pressure is removed it returns, bringing with it the fragments of stone, which fall into the receiver. This washing-out process is continued until all the debris has been removed.

The conditions which warrant the introduction of a lithotrite for crushing stone and the removal of the fragments with the evacuator, are a sound urethra, and a stone not too large nor too hard.

Some preparation is usually necessary before an operation of this kind is resorted to. The urine should, of course, be examined to determine the presence or absence of kidney disease, which must exert a determining influence on the operative procedures proper to be adopted. The patient should be kept quiet for a few days before the operation, and the bowels should be opened early in the morning of the day of operation.

This operation is not suited to cases of stone in children, and a large proportion of the cases of vesical calculus occur before the age of twenty years. In children, the cutting operation is the proper one.

Before commencing the operation, I pass a sound into the bladder to see if I detect the stone. This is very important, and should always be done. It is deemed of such vital importance that, although the surgeon may have felt the stone a dozen times before, but does not feel it at the time of operation, he does not cut. You may think that this is unnecessary caution or precaution, but that it is a wise rule, there is no doubt; for on several occasions the bladder has been opened with the expectation of finding a stone, and no calculus has existed, although at previous examinations the operator thought that he had detected it. Placing this deal-board on the end of the sound, I think that the clink of the instrument against the calculus can be heard over the entire room. There is, therefore, no question in this case as to the presence of a calculus.

We bring the patient across the bed and throw into the bladder about four ounces of flaxseed tea. We must then wait and see if the bladder will retain it. The patient is not yet thoroughly under the influence of the ether, and it seems to me that the bladder is about the last part to yield to an anæsthetic. The object of throwing fluid into the bladder is to so distend the walls of the viscus, that in manipulating the instrument it will not come in contact with the mucous membrane, and thus prevent the wall of the bladder being caught between the blades of the instrument. If too

much fluid is thrown in, it will provoke resistance and be expelled. The patient is not yet fully relaxed, and the stiffness of the knees reminds me of a little incident which occurred in a case which I was cutting for stone, in Delaware about a year ago. The patient was placed on the table preparatory to operating, and notwithstanding the profound anesthesia, the knees could not be bent. On examining the joints, I found false ankylosis on both sides. The adhesions were broken up, and I then proceeded with the operation. In cases in which relaxation does not occur, it would be well to examine and see if a trouble of this nature existed.

I now introduce the lithrotrite, and at once catch the stone. As soon as I secure the concretion, I draw the instrument away and raise it up a little so as to place it clear of the mucous membrane. Having crushed the stone, I pick up the different fragments. After once catching the stone, it is, as a rule, not difficult to catch the fragments, because they all fall to one place. I continue this until the calculus is pretty well reduced.

I next remove the lithrotrite and insert a large catheter, and attach the rubber bag. A portion of the liquid is then slowly forced into the bladder, and as it returns it brings with it some of the debris resulting from the crushing of the stone. This you can see falling into the glass receptacle. It is necessary to let a few minutes intervene between the injections, so as to allow any fragments which may be floating in the liquid to settle into the receiver; for if they were forced back into the bladder, their sharp edges coming in contact with the mucous membrane might cause injury.

A large quantity of debris has now been removed. I shall withdraw the catheter and pass a sound, to see if I can detect any fragments. I can feel none.

The after-treatment will consist in the administration of a suppository of opium, the application of a large poultice over the epigastric region, and perfect quiet. He will be placed on a liquid diet, consisting largely of milk. He will be allowed to drink flaxseed tea, or what answers very well, water containing a small amount of bicarbonate of sodium. Before he leaves the hospital, a sound will again be passed to see if any fragments have been left behind.

CLINICAL NOTES.

BY W. F. COOMES, M. D.

Professor of Physiology and Diseases of the Eye, Ear, Throat, and Nose, in the Kentucky School of Medicine at Louisville, Ky.

Case 1. Master F., aged nine years, was brought to me in the latter part of December, 1883, by his father, who informed me that the little fellow had a pin in his throat, and at the same time said: "Doctor, you will have little trouble in removing it, for the head of the pin is pushing out against the skin."

I paid but little attention to what the man said about the matter, as I thought that he was mistaken about the locality of the pin, and proceeded to examine the larynx with the laryngoscope. This I found very difficult, as the throat had been

manipulated by another physician and by the child's mother, and in consequence of that fact was extremely sensitive and bleeding; but nevertheless I succeeded in getting a moderately fair look at the larynx and its surrounding structures, and could not see the pin.

I then examined the outer surface of the neck at the point indicated by the father, which was near the median line, and a little to the left, and just below the inferior margin of the thyroid and cricoid cartilages.

It was impossible to determine whether the protruding portion was the head or point of the pin, as it was covered by the skin and deep fascia.

The pin moved up and down with each act of deglutition, but did not change its relations with the larynx, showing that it was very firmly fixed.

Being unable to determine whether or not the head or the point of the pin was projecting, it was impossible to say just what means would have to be resorted to in order to remove it.

Under these circumstances, I prepared to do tracheotomy, or whatever might be necessary to remove the pin. I determined, however, not to give an anesthetic until I found that it was absolutely necessary. My little patient, who was quite a soldier, promised me to hold still while I made an incision through the skin and fascia. This he did, and, to my gratification, when I cut through those structures, the head of the pin presented itself. It was firm and fast, and required quite a stout pull with a strong needle-holder to remove it. Indeed, it was necessary to press the larynx backwards and keep it in position with my left hand, while I did the pulling with the right. The pin was so firmly grasped by the tissues that it was considerably bent in pulling it out. Its removal caused but slight pain, and the little wound was closed with a piece of adhesive plaster. There was not a bad symptom following the operation, and the boy attended school as usual after the fourth or fifth day had passed.

The puzzling question is: How did the pin make its way through the tissues as above stated?

Poisoning from Local Application of Iodoform to an Ulcerated Larynx.

Case 2. Dr. S., aged 24, subject of laryngeal phthisis, consulted me in August, 1883. At that time there was considerable ulceration of the epiglottis, with more or less congestion of all the structures surrounding the larynx. There was much pain accompanying the act of deglutition, and in order to alleviate this, iodoform was blown into the larynx once in twenty-four hours. During the time that I made the applications, about two grains was used at each sitting. When the doctor ceased to visit my office, he made the application himself, and used about one grain; applying that with a small insufflator. There were no ill-effects from the drug until after it had been used about thirty days. One evening, about 8 o'clock, the application was made as usual, and in about an hour and a half the pulse became irregular, frequently losing a beat or two. At times the heart's action became much accelerated, and made the patient very uncomfortable. It again became slow and intermittent. Along with this irregular action of the heart, there was a sense of extreme fulness about the stomach, as if

that viscus was distended with gas. There was also a fainty feeling, with a sense of oppression about the heart and lungs.

These unpleasant symptoms lasted about two hours, leaving the patient with an irregular heart, and somewhat exhausted. The application was repeated time and again, with the same result in each instance, thus leaving no doubt about the unpleasant symptoms being due to the action of iodoform.

I must confess that I was surprised when the doctor told me of his experience with the drug; and I would have been loth to believe it, had it not come from one whom I know to be fully competent to judge of its effects. Previous to this occurrence, I was of the opinion that it would be impossible to poison a person by applying so small a quantity of iodoform locally; as we have been told by those who use it extensively, that large wounds could be filled with it, and that there was but little danger of poisoning.

Of course, it is known that poisoning from this drug is liable to occur, when it is applied to open wounds; but it is understood that bad results from such practice are of rare occurrence, and the majority of surgeons apply it without hesitation.

It must be understood that in this instance the open surface was being constantly increased; and this may account for the fact that the patient was not poisoned from the first applications. I am positive that the amount applied by the doctor himself did not exceed one grain, for I had him to measure out what he supposed to be equivalent to the amount applied at each sitting, and found it to be just barely one grain. I report this case simply because the poisoning resulted from so small a quantity of the drug; and in order that others might profit by the experience.

Case 3. J. D. F. R., aged fifty-six years, was brought to me by Dr. Morris, of Elizabethtown, Ky., about August 20, 1880.

The patient was much emaciated, and his general health anything but good. He slept badly, and had an anxious expression about his face. He had a severe cough, which was worse at night and in the morning, and altogether the patient looked very much like an individual suffering with pulmonary phthisis. His vocal cords were examined, but presented nothing more than slight congestion. His lungs were examined by Dr. F. C. Wilson, who was unable to detect anything wrong with them. He was sent home with instructions to have a good diet, with tonics.

I heard no more from the patient for several months, when I received a letter from Dr. Morris, containing a small hickory splinter, a little less than one line in width, and about one inch and a quarter in length. This was expectorated by the patient while in a fit of coughing. This was the cause of the three years' distress; and when it was expectorated, the patient remembered the time of its introduction to have been on a certain evening while he was engaged at work in an axe-handle factory.

He thought the severe cough which occurred at the time that the splinter was introduced, was caused by a great effort that he was making to lift a heavy piece of timber, not dreaming that the piece of wood had passed into his trachea. At the time of the accident, the patient came near

suffocating from the effects of prolonged cough, which lasted for hours, and to use his own expression "the cough was killing."

It is needless to say that the removal of the splinter brought relief, and Mr. R.'s cough ceased, and he has since enjoyed good health.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

The Bacillus Tuberculosis and the Etiology of Tuberculosis. Is Consumption Contagious!

Second Communication.

[Read November 14, 1883.]

BY H. F. FORMAD, B. M., M. D.,

Lecturer on Experimental Pathology and Demonstrator of Morbid Anatomy in the University of Pennsylvania;
Mütter Lecturer in the College of Physicians of Philadelphia.

GENERAL CONSIDERATION.

A little over a year ago* I had the honor of presenting for your consideration some anatomical points in refutation of the etiological relations of the bacillus tuberculosis.

At that time I announced some original observations regarding the histology of scrofulous tissue, tending to place the question of heredity in tuberculous disease upon an anatomical basis. These peculiarities of scrofulous tissues, I submitted as elucidating the etiology of tuberculosis, showing that the peculiar etiological condition of the individual, under the influence of simple irritants, and not the character of the irritant, is responsible for tubercular inflammation. It gives me pleasure to state that these observations have since been confirmed by several competent histologists, whose articles on this subject will soon appear in print; besides which, a general interest has been manifested by favorable comments both in America and abroad.

Shortly before the publication of these observations, Koch, of Berlin, had brought forward the discovery of the now famous bacillus tuberculosis, affirming it to be the sole cause of pulmonary phthisis, and other forms of tubercular disease, and claiming for it, besides exclusive pathogenetic properties, special morphological and chemical characteristics.

In my first paper, I denied some of these propositions upon grounds of personal investigation, and, subsequently, Koch's researches were also severely criticised by a number of other observers.

As interesting and valuable as the discovery of Koch is, from a biological standpoint, its practical value is, in my opinion, decidedly over-estimated, and has not nearly the significance for medical science which the enthusiastic followers of Koch ascribe to it. The influence of the discovery was, however, great in strengthening the traditional and unwarranted belief in the contagiousness of phthisis, as held by a small part of the profession

*Studies from the Pathological Laboratory of the University of Pennsylvania, xi.: "The Bacillus Tuberculosis and some Anatomical Points which suggest the Refutation of its Etiological Relation with Tuberculosis, by H. F. Formad." Read before this Society, October 18, 1882.

and community. On the other hand, this belief led to the popularity of the discovery. In this respect, the bacillus theory has perhaps been harmful, and, taking the consequences into consideration, we should not accept such a theory without the closest scrutiny.

Two practical benefits may accrue from this discovery. The first is that the fear of the effects of the bacillus may induce greater cleanliness in hospital management, and enforce improvement in hygienic matters in general. It is doubtful whether the removal and prompt destruction of the sputum would have any influence in checking the spread of phthisis, as the disease is found as often, if not oftener, in the clean palaces of the wealthy as in the unclean huts of the poor. The second benefit resulting from the bacillus theory may be that physicians may become induced to make more use of the microscope in diagnosis; yet, in this respect, the general use of the microscope is hardly practicable on account of the thorough technic and experience required.

To-day, while the bacillus is acknowledged as a common morphological concomitant of tubercle, the pathogenetic properties are denied it by the best pathologists and clinicians, on account of a want of sufficient confirmation of the evidence thus far offered.

The followers of Koch's theory are, however, numerous, but they are recruited largely from the ranks of clinical teachers, book-writers, and others possessing no opportunities for personal investigation.

It may be well to state that, upon my visit to Koch last summer, made with the purpose of doing justice to this important question, I was gratified in many respects. I found Koch an earnest and conscientious worker, and not as dogmatic and extreme in his views as would appear from his writings; nor is he as self-satisfied and as rash to jump at conclusions as are some of his followers. Koch has the co-operation of an excellent staff of assistants, all able mycologists; but it was a matter of surprise to me that there was not a single competent pathologist connected with Koch's laboratory; and such services are evidently much needed to give to the observations made there the proper interpretation from a biological and anatomical standpoint. I was also pleased to learn in Berlin that the discovery of the bacillus was exaggerated, not so much by Koch himself as by the Imperial Board of Health, which employs him, and by his over-zealous followers in the profession. There is strong evidence, however, that Koch's investigations are biased by the determination to find for each specific disease a specific fungus.

Following out the various phases in the study of tuberculosis, I am sorry to see that the entire subject is now being considered from a purely etiological basis with reference to bacteria, while the study of the anatomical and biological relations is wholly neglected.

I admire the beautiful bacteridian discoveries of Klebs, and particularly those of Koch, in connection with the etiology of tuberculosis. The accomplishment of these results is a triumph for mycology and scientific botany; but these studies are much too one-sided to have an application to scientific medicine. The bacillus is there! It is concomi-

tant with most tubercular lesions. It is diagnostic of tuberculous change. It is, on account of its irritant properties, one of the causes of tuberculosis; but this forms no reason for asserting that tuberculosis should be considered a contagious disease, without further investigation and proof. A contagious disease can have only one cause. I cannot agree with those who define the predisposition to phthisis as being a condition of the organism which offers a favorable soil for the tubercle bacillus. Nor can I believe that inheritance is explained by subsequent infection from cohabitation; *e. g.*, that children become scrofulous by living with consumptive parents.

The latest fruits of the bacillus studies have even inspired Baumgarten (*Centralblatt f. d. Med. Wis.*, Aug. 4, 1883,) and several others to come to the conclusion, in reference to the hereditary nature of tuberculosis, that the bacillus is transmitted in its larval state from mother to foetus in intra-uterine life! One would think, however, that one of the most wonderful effects of the tubercle bacillus is manifested by the change it produced in the direction of reasoning of some of our pathological and clinical investigators, both at home and abroad.

Some of the younger pathologists are even affected by a regular fanaticism for bacterian studies in tuberculosis. These studies now take the place of their former excellent pathologico-anatomical studies. Consideration is no longer given to the tissue changes, or the nidus which invites the bacteria and nourishes them. In fact, Koch's followers in their enthusiasm exaggerate matters, and, to Koch's own amusement, go further in their bacillus speculations than he himself thinks justifiable. It is really painful to read how some of the younger German pathologists, and a few of the prominent English surgeons, under the influence of the bacillus craze, will make, in their publications, assertions entirely unwarrantable. They describe, for instance, with the greatest ingenuity and exquisite minuteness, how "one or more bacilli" will produce certain histological changes in the lungs or in the peritoneum, designating the exact route to the same; how the different cells, the lymphatic and the blood-vessels, are affected; how the bacilli convert one variety of cells into another; how they manufacture giant cells and cheesy material; how acute and chronic phthisis is produced by the bacilli, and the quantity necessary for each; how tubercles develop only and exactly in those places where the bacillus becomes lodged; how, if bacilli alone are inhaled, miliary tubercles form; and how, if the bacillus is accompanied by some other irritants, a broncho-pneumonia will ensue.

All the above statements are made by scientific medical men and pathologists, and offered as broad facts, in full earnest! I only have to say that here evidently observation is substituted by imagination and speculation; and all this is done for the sake of the convenience in explaining a disease by pretty hypotheses.

The only men who attempted to repeat Koch's experiments, besides the work done in the pathological laboratory of the University of Pennsylvania, were Spina (*Studien über Tuberculose* Wien, 1883,) and Watson Cheyne. Of the latter

two scientists, Spina came to results entirely different from those of Koch, and they disprove beyond doubt some parts of Koch's hypothesis. From an analytical and critical point of view, Spina's studies of tuberculosis are excellent, but the technical part of his investigation is deficient, and hence not satisfactory. Watson Cheyne, to whom the "British Association for Advancement of Science by Research" had entrusted the investigation of tuberculosis, and the testing of Koch's researches, did not do justice to his mission. From Cheyne's report (*The Practitioner*, April, 1883), it is seen that he made no earnest attempt to study the nature of tuberculosis, because all he did was to study and experiment with bacteria met with in tuberculous lesions. He went to see some of the different mycologists, consulting only believers in the germ theory; obtained some French and German bacteridian material, and, after testing the same, he reports with great emphasis that Koch's bacilli are a more genuine tubercular virus than Klebs' or Toussaint's micrococci. He did not inquire, nor did he care, whether tuberculosis may have any other cause! He simply imitated some of Koch's experiments with the bacillus material in rabbits and guinea-pigs (only), and obtained, of course, the same results. Furthermore, he made some control experiments, which, as I will show, pass for naught, as they are much more deficient than those of Koch.

There are a number of excellent studies in reference to the occurrence of bacilli in the sputum and in tuberculous tissues; but the main part of Koch's hypothesis, *i. e.*, the etiological relation of these bacilli to the tubercular disease, remains still unconfirmed.

My own researches on tuberculosis were made from a standpoint different from that of Koch, and they were undertaken five years ago, being carried on continuously since that time by myself and assistants. My object was to investigate the natural history of the disease, without being influenced by any preconceived views. While due attention was paid to external agencies in the production of tuberculosis, the part played by the animal or human organism itself, the behavior of its component cells, and the primary changes in the tissues, were not lost sight of.

I may state that I was fortunate enough to be able to utilize the material of over four hundred cases of tubercular disease from the autopsy table, including a number of cases studied in the pathological institutes in Europe at various times.

My present research on tuberculosis with special reference to the bacillus question, was carried on during the last year and a half, under the auspices of the Provost of the University of Pennsylvania, Dr. Wm. Pepper. This communication should not be considered a report on my investigations, as these are not yet concluded; but a detailed report of these investigations will be made next summer. Some of the positive results achieved will, however, be referred to in the present paper; otherwise it merely embodies a general critical survey of the question of the etiology of tuberculosis, based upon a careful perusal of the literature of the subject and upon personal observation.

I may state at the outset, that, while the results of my observations force me to-day to make

some concessions to Koch, namely, that his bacillus, on account of its irritative properties, can produce tuberculosis under certain conditions, I am firmer than ever in my former conclusions from the results of repeated observations, that tuberculosis may arise from other causes. The bacillus may be one of the causes, conditionally, but it is not the cause. The question of predisposition stands in the way of the acceptance of the bacillus theory. Furthermore, I will try to show that tuberculosis is not a contagious disease, and it is particularly in reference to this that I am glad to bring the present subject before the Society, desiring to profit by the discussion which is to follow as a result of the experience and the clinical observation of the individual members of the Society.

The question of the contagiousness of phthisis is one of supreme importance, not only from its scientific, but also from its social aspects.

For convenience in treating the subject of the etiology of tuberculosis, I shall speak of it under the following headings:

1. The definition, the anatomical character, and the etiology of tubercular lesions, including pulmonary phthisis.
2. The predisposition; the predisposing conditions; scrofulosis.
3. Tuberculosis without predisposition due to inflammation of serous membranes.
4. Question of contagiousness; clinical aspect.
5. The bacillus tuberculosis.
6. Experiments—"pro" and "contra;" traumatic tuberculosis.

Conclusions.

All these considerations will have to be, of necessity, very brief.

1. The Definition, the Anatomical Character, and the Etiology of Tubercular Lesions, Including Pulmonary Phthisis.

No definite understanding concerning a disease can be arrived at unless some fixed conception of the anatomical characters and various expressions of the lesions of that disease is formed. Thus, as regards the question of tuberculosis and pulmonary phthisis, the matter would be much simpler if a general understanding could be arrived at as to the definition of tuberculosis and phthisis in its different anatomical manifestations. The pivot of the question is, what to call a tubercle, or a tubercular lesion.

The traditional conception of a tubercle being a miliary node, the belief is that nothing is tuberculosis unless expressed by nodes, and that everything is tuberculosis that appears to the eye as containing nodes. These misconceptions are what bring the confusion and prevent the settlement of the question of tuberculosis, both at the post-mortem table and in the hands of the experimenter.

One of the results of this confusion is that some clinicians divide pulmonary phthisis into catarrhal, cheesy, fibroid, and tubercular proper, because they do not see tubercle nodules in some of these forms of phthisis. They seem not to be aware of the fact that miliary tubercles do not belong necessarily to the picture of pulmonary phthisis; and, on the other hand, that those nodes which occasionally appear as miliary tubercles are not miliary tubercles at all, but are only

miliary foci of broncho-pneumonia, due to aspiration, as will be explained later. Miliary tubercles, if at all present, usually form a part of a general disease, a tuberculosis of the whole body. In rare instances, when the miliary eruption takes its departure from the lung, the miliary nodules may be limited to the lung.

A more serious matter is the mistake that experimenters make of interpreting as tubercles the so-called inhalation tuberculosis, artificially produced in animals by means of a spray with tuberculous and other matter. The nodules produced in the lung under these circumstances are not miliary tubercles—in fact, no tubercles at all. They are simply miliary broncho-pneumonic foci, limited to those terminal collections of air-vesicles, called acini, in which some of the inhaled irritative material became lodged. The natural round boundaries of these acini correspond exactly to the usual size of miliary tubercles, and appear as such even under the microscope, although filled merely with an unorganized inflammatory exudate. The uniform distribution of these foci is due to the fact that the inhaled irritating particles are distributed only to individual and the most accessible bronchioles and acini, thus simulating a true miliary tuberculosis of the lung. Similar broncho-pneumonic foci occur in the human lung from self-aspiration of tuberculous material from a primary focus to some other portion of the lung or throughout the whole lung. This was proven long ago, but the inhalation experimenters appear not to be aware of that fact. Careful personal observations and experiments, to be recorded in my forthcoming report, have convinced me that such inhalation experiments prove nothing, either for or against the contagiousness of tuberculosis, in connection with which they have been brought forward as the strongest affirmative proofs. Furthermore, it must also be remembered that the so-called experimental inhalation tubercles, as a rule, remain local.

On the other hand, miliary nodes or tubercles are met with, not only in tubercular lesions, but also in a variety of similar and dissimilar lesions, such as pearl disease or bovine tuberculosis, lupus, leprosy, glanders, actinomycosis, chancre, and gummata, cancer, typhoid infiltration, lymphomatous and leukæmic lesions. All these lesions, even cancer ("miliary carcinosis"), are able to give rise to exquisite miliary disseminations, or eruptions, although these are most frequently observed in tuberculosis. We already recognize leprosy, lupus, glanders, syphilitic, and other tubercles, in contradistinction to tuberculous or serofulous tubercles.

To the above nodular formations may be added a variety of minute inflammatory foci of granulation tissue organized around minute foreign bodies introduced experimentally into various tissues; also, "false tubercles," such as mere unorganized collections of lymphoid cells, held together by some fibrine or by some artificial or natural round boundaries, such as is the case with the referred-to "inhalation tubercles;" and further, also, the eruption and follicular enlargements in the skin and mucous membranes.

The question now arises, how to distinguish between these various kinds of nodules, apart from their clinical features. They may all under-

go a cheesy or a fibrous change, may calcify, and may contain giant cells. In all, bacilli may be found if a cheesy change occurs, or tends to occur, save in cancer and in leukæmic formation. Without desiring to appear skeptical, I must say, however, that it takes the skill of a Koch to differentiate, sometimes, the bacilli met with in the various kinds of nodes, even after applying all microchemical tests.

The true tuberculous tubercles occasionally do not show any bacilli whatever, as I will prove from personal observation, and from the reliable testimony of others. It will also be shown that the only test now left for determining the pathogenic peculiarity of tubercle—namely, the asserted exclusive property to produce tuberculosis—is conditional and uncertain, since substances, not tuberculous, may, under similar condition, have the same effect.

Therefore, it is impossible to define tuberculosis, either by its anatomical peculiarity or by the pathogenic property of its nodes.

Another important point in the natural history of tuberculosis is the cheesy degeneration of its products; but here, again, we are surrounded by difficulty if we take only the cheesy product into consideration, because all the lesions mentioned before as being characterized by, and as being capable of, nodular eruptions, have the tendency to undergo cheesy change. Besides this, simple inflammatory products have been observed to undergo a similar change, as is instanced by that form of cheesy hepatization, sometimes following croupous pneumonia, and also by certain forms of rapid necrotic changes, such as occur in acute septic inflammations, designated lately by the name of coagulation necrosis. It must, however, be remembered that the total absence of cheesy masses in the body of tuberculous subjects has been observed.

To tell tuberculosis from allied lesions is only possible after a consideration of the soil in which it develops, and the location of the products, together with the clinical and anatomical manifestations.

What is the origin of tubercle nodules?

The primary occurrence of miliary tubercle nodes is, to my mind, very questionable. I have never seen it occur without the co-existence of diffuse granulation tubercle. This granulation tubercle is recognized by all as being a simple inflammatory granulation tissue, characterized by cells somewhat larger than ordinary lymphoid cells, containing usually giant cells, but undergoing very readily cheesy change on account of its deficiency in blood-vessels. This tissue is regarded by most pathologists as secondary to miliary tubercles; but I think, after careful observation, that the reverse is the case; because I have never seen upon the post-mortem table, or in animals, primary miliary nodes without the granulation tissue, while the granulation tubercle tissue does not exist very frequently without the nodes. Moreover, primary miliary tuberculosis is unknown.

That tubercle is primarily a simple granulation tissue of inflammatory origin has been proven experimentally. E. Ziegler (Centralbl. f. d. Med. Wis., 1874, No. li.) made the following interesting experiment: He inserted below the skin or into the peritoneum of animals, a number of pairs

of glass covers, each pair glued together in such a manner that between them there existed an interspace just large enough to allow the entrance of white blood corpuscles; and these corpuscles, not being severed from the body of the animal, then formed a tissue between these plates of glass, which, upon removal after various periods, could be readily examined under the microscope, and the conditions of tissue formations traced. Under these circumstances it was observed that whenever blood-vessels had developed in the new-formed tissue between the glass plates, an organization of the cells into a perfect connective tissue took place; but when the formation of blood-vessels had failed to occur, then a tissue simulating tubercle tissue was formed, made up of epithelioid and giant cells, and cheesy changes had occurred. Ziegler very properly declared the latter product

to be tubercle tissue. I have had, and have at present, ample opportunity to corroborate the accuracy of these observations. Ziegler's experiments were repeated in the pathological laboratory of the University of Pennsylvania, by Hammer, and at present are being carried on by Woodnut. By these experiments, made with slight modification, after the method of Ziegler, under varying conditions and upon various animals, it was shown that the granulation tissue gradually gave origin to tubercle nodules. Furthermore, these experiments showed that the tubercle nodes and cheesy changes ensue without the action of bacilli, as the latter were found not to be present when proper care was taken, during the execution of the experiment, to exclude them.

(To be continued.)

EDITORIAL DEPARTMENT.

PERISCOPE.

The Influence of Malarious Disorders on Urethral Fever, with Remarks on the Treatment of Stricture.

In the *Brit. Med. Jour.*, February 23, 1884, Dr. John Ward Cousins thus writes:

During the recent debate on urethral fever in the Medical Society of London, the President (Sir Joseph Fayrer), referred to the association which frequently exists between urethral fever and the paroxysmal fevers of malarious climates. He remarked "that the disease is uniformly more severe, and more probable to recur, in malarious climates than in our comparatively temperate one;" and that "persons who have been under the influence of malaria, and have lived in malarious climates, are more liable to suffer from this condition than others." Now, the great practical value of these observations must be very evident to every surgeon who is called upon to treat patients laboring under disorders of the urinary organs, after a residence in a malarial and tropical climate. Many instances have occurred in my surgical practice, proving this association between urinary and malarious disorders, and the necessity of special care in the management of stricture of the urethra under these circumstances. After complete freedom from the disease for a long period of time, the mere passage of an instrument into the bladder is, sometimes, followed by an attack of paroxysmal fever, marked by rigors, elevation of temperature, sweating, and high-colored urine. For example, not long ago, a gentleman consulted me for stricture who had suffered from several attacks of fever some years before, during a residence in the northern districts of India. After many days' rest and preparation, I examined the stricture, and easily passed a soft instrument into the bladder. Within a few hours he had a well-marked fit of ague, and on my visit

the following day, he said to me: "You have brought out a sharp attack of my old fever." The paroxysms occurred regularly for some days, and then subsided, with the aid of quinine, rest, and warm baths. As soon as he was convalescent I sent him away, and in a month or two he returned to me much improved in health. With great caution I commenced again the surgical treatment, and soon cured the stricture without any re-appearance of the old disorder.

The remarkable tendency of malarious fevers to impress a character of periodicity upon subsequent ailments has often been a matter of observation. Their characteristic features manifest a disposition to recurrence after a long series of years, under any shock or depression of the system. Sometimes, prolonged exposure to malarious influence issues in a morbid alteration of a great many organs and tissues; but, even when no trace of structural disease is discoverable, a deep impression is often stamped upon the nervous system. A special liability, however, to the recurrence of paroxysmal fever is observed in connection with disorders of the urinary organs. This is dependent upon the normal sensibility of these organs, and their intimate relation to the spinal and vaso-motor centres. The readiness with which direct stimulation upon them may induce constitutional disturbance, and their proneness to reflex irritation, are indications of their widely spread nervous associations. Now, to this susceptibility must be added the persistent effect of the malarious poison upon the nervous system. Its specific action has long passed away; still there remains behind a nervous instability, which permits a reflection of any impulse through the old tracts, and a reproduction of a disturbance—an exact counterpart of the former fever, attended with all its characteristic phenomena.

In many other nervous and neuralgic diseases, a persistent instability of some central or peri-

pheral part of the nervous apparatus is often a well-marked feature, and many striking examples can be readily recalled, showing that obscure sensibility lingers long in channels once acutely disturbed, and that any sudden depression of the system is often sufficient to arouse long-forgotten pains and morbid sensibilities.

One word in reference to the surgical treatment of malarious patients suffering from stricture of the urethra. It is always necessary in these cases to proceed with the greatest gentleness and caution. The risk of urethral fever is far greater than under ordinary circumstances, and this must be combated at the onset by suitable measures for improving the health and vigor of the system. Great benefit results from tonic treatment and quinine, combined with rest, careful diet, and warm baths.

As regards the surgical management, heroic measures, in my opinion, must be excluded, as both unsuitable and unsafe. Rapid dilatation and splitting are generally out of the question, and will surely be followed by disturbance, stamped with malarious periodicity. Even gradual dilatation cannot be undertaken too cautiously. The operation should always be performed in a warm room, and with the patient well protected with warm clothing. It is my practice to fill the urethra with warm oil, and always to use soft tapering dilators, introduced over a catgut or whalebone guide. The instruments should be very gently manipulated, without causing pain or any mechanical injury. We must always be satisfied with very slow progress, and, during the early stages of the treatment, it is often desirable to allow an interval of several days. With these simple precautions, I have generally found that the urethra soon becomes tolerant of mechanical interference.

Amenorrhœa and Vicarious Menstruation.

Apropos of this subject, it is of value to note the following from the *London Medical Times*, because it bears the authority of no less a name than Dr. Samuel Wilks:

I have been much impressed with the practical importance of the lecture published in this journal by Dr. Matthews Duncan, on "Amenorrhœa and Vicarious Menstruation;" for although the views therein contained are no doubt in accordance with the opinions of many experienced men. I cannot but think that a large number in the profession require to be roused up to their truth. As regards vicarious menstruation, I have never published my opinions on the subject, but as a teacher of students, I have always denounced the absurdity, as well as the error in fact, of a belief in this imaginary disorder. I have had considerable experience of diseases, both in public and private practice, and I am still waiting to see an instance of this curious condition before I can throw off my incredulity. It seems to me that some of the greatest advances in medicine have been not so much by adding new facts to our knowledge, as by getting rid of old wives' fables, which, originating in the dark ages, have finally undergone a kind of glorification in the medical mind.

If there be no such thing as vicarious menstruation,

the subject had better be eradicated from our medical books, and be no longer instilled into the minds of the young, as is now, unfortunately, the case, as I know from long experience as an examiner. Such questions as the causes of hæmoptysis and hæmatemesis are amongst the commonest put to candidates for diplomas, and one never fails to hear much about vicarious menstruation. I have seen my late colleague, Dr. Peacock, at the College of Surgeons—a man of the mildest temper—get really angry when student after student would give vicarious menstruation as the first cause for hæmatemesis, looking over such frequent conditions as ulcers or cirrhosis. The reason was clear: their memory was impressed by the very strangeness and oddity of the disorder, and so it came first to the front.

But lately having had to correspond about a case of hæmatemesis, in which vicarious menstruation was suggested as a cause, I was referred, in consequence of my skepticism, to Watson's lectures, a gospel which could not be gainsayed. I gladly refreshed my memory, but was certainly surprised to find that the author regards this condition as a very common occurrence. It is remarkable, however, that he relates no case of his own, but is content to give particulars of two cases, which date back nearly a century from the present time. Sir T. Watson says, "Women are liable to perverted menstruation (so to call it) through other channels than the natural one. Hemorrhage from the stomach occurring vicariously of menstruation is abundantly common. I told you, in a former lecture, that patients will sometimes menstruate, for years together, through the lungs; more commonly do they menstruate through the stomach." It is very significant that Sir Thomas mentions no case coming within his own knowledge, but is content to relate a case which was told him by Dr. Latham, and ends the story by saying: "This was the woman's own account, and there appeared no reason to question its accuracy." His other case is quoted from Pinel, and is that of a woman who spent her life in the *Sapètrière*: "This woman continued to menstruate through her lungs, at each monthly period, from her 16th to her 58th year, i. e. during 42 years." It may be observed how the change of locality of the function lengthened its activity to a very advanced period of life.

I feel great reluctance in thus criticising so esteemed a writer as the late Sir T. Watson, but the greater the weight of his authority; the more need there is of thoroughly sifting the truth of doctrines of so extraordinary a nature as I have quoted.

As regards the other subject of Dr. Duncan's lecture, amenorrhœa, I will only say a few words, since it is treated as a substantive complaint by many gynæcologists. For my own part, I know nothing of such a disorder, nor of such remedies as emmenagogues. I believe myself that amenorrhœa, like many other complaints, is the remnant of a popular delusion; and if so, it should be eradicated, like the other disorder, from the medical mind. I have a letter in my desk, written by a qualified medical man, in reference to a young lady, the subject of phthisis, in which he says that if I could give an emmenagogue to bring on the menstrual function, he had no doubt the pa-

tient would get better of the chest disease. I wrote back to say that I heartily agreed with him. This is only an extreme example of what one hears daily in cases of chlorosis and other disorders of girls. Feeling, therefore, so much in accord with the sensible opinions propounded by Dr. Matthews Duncan, I trust they will find their due weight on the minds of the younger members of the profession.

The Diagnosis of Mitral Constriction.

The *Med. Times and Gaz.*, January 5, 1884, says:

Simple mitral constriction is of far more frequent occurrence than is generally allowed, and its diagnosis probably presents greater difficulties than any other serious lesion of the valves on the left side of the heart. We exclude from consideration cases which are complicated by regurgitation, because the latter, when advanced enough to produce grave symptoms, is easily detected; and the presence of constriction as well in such cases is not of great practical importance. But when, as not rarely occurs, the question is whether stenosis of the mitral orifice be present, and the cause of serious symptoms, or whether the heart be healthy, and the distress and danger due to other conditions, accurate diagnosis becomes a matter of the utmost moment. In a typical case the observer feels a thrill at the apex preceding the impulse of the heart; he hears at the base a clear second sound over the aortic valves, an exaggerated one to the left of the sternum, and at the apex a rolling presystolic murmur, gradually increasing in intensity and leading up to a short and sharp first sound, which is not succeeded by any appreciable second sound. The diagnosis of mitral stenosis under such circumstances admits of little doubt.

But in a second series of cases both murmur and thrill may be absent, and the heart's action regular; and the difficulty of detecting the disease then becomes great. The most striking auscultatory phenomena are accentuation of the second sound at the base to the left of the sternum, and, what is of much greater importance, a peculiar hesitation in the production of the first sound, a kind of hanging fire, which is easier for the experienced auscultator to appreciate than to describe. Whatever be its origin, whether it be a faint sound caused by the blood passing through the constricted orifice into the ventricle, and so practically a murmur, or be due to a slowly beginning, though suddenly ending, ventricular contraction, it is a phenomenon which at once strikes the ear and suggests the nature of the disease. In these and all other cases of suspected constriction of the mitral orifice, the detection, if possible, of increase in size of the left auricle and right side of the heart, yields valuable corroborative evidence.

There is a third class of cases, in which there may be no murmur, no thrill, no hesitating first sound, but extreme irregularity of the cardiac action, the beats being very frequent and very irregular both in rhythm and in force; so much so that a great many of them produce no pulsation at the wrist. In some cases as many as half the beats of the heart are not felt in the radial artery,

so that the pulse there may be moderate in frequency, although the cardiac contractions succeed each other with extreme rapidity. Similar phenomena may likewise be observed in cases of simple dilatation of the heart with degeneration of its walls, such as occurs, for example, in chronic bronchitis and emphysema; but then the patient is usually past middle life. If grave cardiac symptoms be found in a comparatively young person, and if auscultation only reveal extreme irregularity in the heart's action, the presence of mitral stenosis ought to be at once suspected. The administration of digitalis in such cases not only often removes the patient's distress, and produces regularity and normal frequency of the heart's beats, but also facilitates diagnosis. For when the heart's action gets slow and regular, a presystolic murmur frequently makes its appearance.

Finally, there are cases of considerable mitral constriction which produce no sufficiently well-marked morbid phenomena to enable the observer to detect the presence of heart disease. But the pathologist not infrequently meets with these narrowed orifices in the post-mortem room in patients who have died from other diseases. The reflection is then forced upon him, how extreme some pathological conditions require to be, before they come within range of our present powers of diagnosis.

Anuria from Compression of Ureters by Cancerous Disease.

To the Boston Society for Medical Improvement (*Boston M. and S. Jour.*, March 6, 1884), Dr. Minot showed the specimen, which was taken from a woman fifty-three years old, who entered the Massachusetts General Hospital February 13, and died February 21. She was a widow; never had children or miscarriages. For about three years she had occasionally observed slight discharges of blood from the vagina. For the past six months there had been slight leucorrhoea, soreness above the pubes, frequent micturition, and occasional painful defecation. For four weeks there had been great thirst, polyuria, and itching of the arms and of the anus. She had lost much flesh and strength, but had been in bed only nine days. She was anæmic and sallow. Temperature 99.8° F., pulse 120, respiration 26. On the 14th she passed sixteen ounces of urine in twenty-four hours. This was examined by Professor Wood, who reported it as pale, specific gravity 1008½, neutral, a slight trace of albumen, very large excess of bladder and vaginal epithelium, and also clumps and isolated large spindle-shaped and caudate cells, suggestive of morbid growth, a little blood and pus. On the 15th, one ounce of urine was drawn by catheter, and from that time, during the remaining six days of her life, the patient passed no urine, except about two drachms with a defection on the 18th. She vomited everything taken, and her breath had a urinous odor. The vomitus of the 20th, also examined by Professor Wood, was found to contain 6.7 grammes of urea to 912 cc. There was pain in the right flank. She retained consciousness to the last, although drowsy much of the time.

The autopsy, made by Professor Fitz, showed that the enlarged uterus filled the pelvis, and was

adherent to the bladder and rectum and to the pelvic walls. The bladder contained half an ounce of turbid urine. On its posterior wall was an ulceration three-quarters of an inch in diameter. The uterine cavity was four inches in depth; the os externum readily admitted the forefinger. The substance of the uterus was transformed into a uniformly opaque, white tissue, from which on pressure sebaceous-like plugs were squeezed. This change extended to the fundus, where there was a round, laminated nodule, easily crushed, but with no sebaceous-like plugs. The left ureter was dilated and tortuous, and obliterated for an inch and a half at the vesical end by means of a soft gray new formation. The left kidney formed a sacculated tumor of the size of the fist, only a thin seam of renal tissue being left. The right ureter was dilated, the vesical opening was the size of a pin, and the course of the vesical end tortuous. The right kidney was half as large again as the left, its surface grayish-white, the cortex easily detached, increased in thickness, anæmic, not opaque; tubular regions indistinct; pelvis moderately distended. Lymph glands over promontory of sacrum enlarged to the size of an English walnut; on section white, and homogeneous, and numerous sebaceous plugs were squeezed out on pressure.

An interesting feature of the case was the diagnosis of morbid growths by means of the microscopic examination of the urine; also the evidence of the partial elimination of urinary constituents by the lungs, and probably also by the mucous membrane of the stomach. The preservation of consciousness along with urinary suppression is remarkable, but not very unusual. Dr. Minot had before reported to the Society a similar instance. The treatment consisted mainly in the subcutaneous injection of pilocarpine, in the hope of relieving the kidneys through vicarious action of the skin. Dr. Minot showed two microscopic specimens, kindly prepared by Dr. H. F. Vickery; one was taken from the enlarged glands in the lumbar region, and the other from the uterine tissue. They showed the characteristic alveolar structure of flat-celled cancer.

Lesions of the Eye Due to Rheumatism.

From a foreign exchange we learn that Professor Panas lately delivered a very interesting lecture at his clinic at the Hôtel Dieu on this subject. He began with the statement that the relation between affections of the eye and the different diatheses was little known among the ancients, and it was only at the end of the last century that the idea of connecting rheumatism with diseases of the eye was entertained. The classification of ocular affections was somewhat confused as regards the diathesis. Thus we find acute glaucoma classed among the rheumatic affections of the eye. In our own time there is less confusion in the classifications; but, notwithstanding the improved methods of diagnosis at our disposal, there is yet a great deal to be done in the way of assigning each disorder or group of disorders of the eye to its proper diathesis. For instance, iritis is, for the most part, ascribed to syphilis; it is, indeed, the tendency of the day to put down almost every manifestation of disease to that affec-

tion. According to M. Panas, the proportion of iritis due to syphilis is not nearly so great as is generally given in classical works on ophthalmology, and a larger margin may be left for rheumatismal iritis, with which iritis of syphilitic origin is so frequently confounded. The one is perfectly distinguishable from the other, the former assuming always the serous form, whereas the latter assumes the plastic form. Rheumatismal iritis is, therefore, also termed serous iritis, and is accompanied by extravasation of fluid into the anterior chamber of the membrane of Descemet, which M. Panas considers pathogomonic of this affection. Moreover, the synechiæ that are produced in rheumatismal iritis are easily broken; this is an important element in the prognosis of the disease, and is to be met with only in rheumatic subjects, particularly of the chronic form; it is very frequently also found among gouty individuals, but it exists rarely as a complication of acute articular rheumatism. The cornea is less susceptible to the influence of rheumatism; and, strange to say, the sclerotic is not mentioned in this connection, as *a priori* the fibrous nature of this membrane would seem to point to it as the seat of predilection of the manifestations of a rheumatic or gouty nature. After entering into considerations of other parts of the eye in connection with rheumatism, Prof. Panas stated that ophthalmologists are as yet undecided as to classifying conjunctivitis among the manifestations of rheumatism, as it is so easily confounded with conjunctivitis resulting from other causes. As regards treatment, the lecturer dwelt upon the necessity of combining general with local measures, keeping in view the diathetic connection that may exist between the rheumatism and the ocular affection, without which the treatment must end in a lamentable failure; thus, salicylic acid for the rheumatic diathesis, mercury for the syphilitic, colchicum for the gouty, and iodine for the scrofulous.

Visceral Lesions in a Case with Epileptiform Attacks.

To the New York Pathological Society Dr. R. W. Amidon gave the history of a case of epileptiform attacks occurring in a boy seven years of age, of very bright intellect, coming from a neurotic family. When three years of age he suffered from measles, which were followed, according to the mother's statement, by general oedema; and at about the same time spells developed, which were treated by the attending physician with bromide of potassium, ten grains three times a day. At the time when Dr. Amidon saw the patient, there was an eruption from bromism upon the legs, face, and forehead, which readily disappeared on discontinuing the medicine. Respecting the attacks, Dr. Amidon said the following facts were against the idea of epilepsy: first, he had never known a person to have seventy-two regular epileptic convulsions in as many hours, and yet retain comparatively good health and a clear head, as this patient had done. Second, the child had a distinct recollection of each convulsion, and was always able to foretell their occurrence. Third, it never uttered a cry before the convulsion. Fourth, it never bit the tongue, nor frothed at the mouth. Fifth, there was preserva-

tion of sensibility and resistance to opening the eyelids during the attack. Certain of these facts led to a diagnosis of hystero-epilepsy and a favorable prognosis. The remedies employed in the treatment were aqueous extract of opium, cannabis indica, quinine, iron, tonics, regulation of the diet. There were symptoms of improvement under treatment, but relapses occurred. Death finally took place from œdema of the lungs and heart-failure. At the autopsy, the stomach was found dilated, the spleen enlarged and congested, the kidneys congested, with atrophy of the cortex. The right ventricle of the heart was dilated, and there was fatty substitution in its walls; the left was concentrically hypertrophied; the right auricle was thinned and dilated. The brain was normal and well developed. Had the condition of the stomach been recognized during life, he should at once have resorted to hypodermic medication.

REVIEWS AND BOOK NOTICES.

BOOK NOTICES.

Estudios Clínicos de Neuropatología. Per Jose Armangué y Tuset. 1 vol., 8vo., pp. 244. Barcelona, 1884.

The study of the nervous system, in its various relations, has long occupied the attention of Dr. Armangué, and in this volume he collects a number of articles which he has from time to time contributed to the medical press on this subject. They are characterized by extensive reading, and also by the fruits of close clinical observation. He combines a thorough theoretical knowledge, with the habit of bringing it to bear on points in practice, which is something always pleasant to note in an author.

Practical Pathology. By G. Sims Woodhead, M. D., Demonstrator of Pathology in the University of Edinburgh. With 136 Colored Plates. 8vo., pp. 484. Philadelphia: H. C. Lea's Son & Co.

There are many treatises on pathology, but none devoted to the methods of studying, examining, and preparing morbid tissues. This want the author of the above work aims to supply; and he has succeeded in a very creditable manner. His directions are full and clear, and the numerous illustrations, in colors, of morbid products, natural and stained, are really beautiful.

The first chapter defines the methods of making a post mortem examination. The remaining thirteen take up one part or organ after another, explain its normal structure, and then recite and illustrate the various pathological changes to which it is liable, with the appropriate treatment to develop its microscopic character, and to prepare it for demonstration. To the student of pathology who knows how to handle his micro-

scope, we can recommend no better book than this as a guide in his investigations.

The Cinchona Barks, Pharmacognostically Considered. By Friedrich A. Flückiger, Ph. D. Translated, with Notes, by Frederick B. Power, Ph. D., Professor of Pharmacy in the University of Wisconsin. Philadelphia: P. Blakiston, Son & Co. Price, \$1.50.

Prof. Flückiger, of Strasburg, is one of the highest living authorities on drugs, and this monograph is worthy of his reputation. It treats of the botanical origin and species of cinchona, its natural habitat, varieties, its culture in different parts of the world, spurious barks, chemical constituents, estimation and manufacture of its alkaloids, history of its introduction, and bibliography of the subject. Eight lithographic plates, of a botanical character, are appended.

The translation leaves something to be desired. The German idiom is occasionally followed so closely that the sentences are obscure.

The International Encyclopædia of Surgery. Edited by John Ashhurst, Jr., M. D. Vol. IV., pp. 987. William Wood & Co., New York.

The contributors to this volume of this important work are Dr. John H. Packard, on injuries of the bones; Mr. Richard Barwell, M. R. C. S., on injuries of the joints; Dr. John Ashhurst, on excisions and resections; Dr. George E. Fenwick, on excision of the knee-joint; Mr. H. T. Butlin, M. R. C. S., on tumors; Dr. John A. Lidell, on injuries of the back; and Mr. F. Treves, M. R. C. S., on malformation and diseases of the spine.

Of the general excellence of the work it is superfluous to speak. Each of these writers contributes a careful monograph on the subject of his choice, and the reader cannot complain of anything but an excess of matter. There is perhaps too diffuse citations of cases, and the bulk of a large octavo of a thousand pages is rather discouraging to the average reader.

In an examination of the several articles, that by Dr. John H. Packard, on fractures, and that by Mr. Butlin, on tumors, have impressed us as being particularly satisfactory, the matter being exceedingly well arranged, and presented with great clearness and compactness.

Quite a number of lithographs, plain and colored, and wood cuts, embellish the volume, and add to its usefulness.

—Last year the students at Edinburgh University numbered three thousand three hundred and forty. When its new buildings are completed it will be the largest university now existing.

THE
Medical and Surgical Reporter,
A WEEKLY JOURNAL,
ISSUED EVERY SATURDAY.

D. G. BRINTON, M. D.,
JOSEPH F. EDWARDS, M. D., } EDITORS.

The terms of subscription to the serial publications of this office are as follows, payable in advance:—

Med. and Surg. Reporter (weekly), a year,	\$5.00
Quarterly Compendium of Med. Science, -	2.50
Reporter and Compendium, - - - -	6.00
Physician's Daily Pocket Record, - -	1.50
Reporter and Pocket Record, - - - -	6.25
Reporter, Comp. and Pocket Record, - -	7.00

For advertising terms address the office.

Marriages, Deaths, and Personals are inserted free of charge.

All letters should be addressed, and all checks and postal orders drawn to order of

D. G. BRINTON, M. D.,
115 South Seventh Street,
PHILADELPHIA, PA.

THE
QUARTERLY COMPENDIUM
OF
MEDICAL SCIENCE.

The COMPENDIUM, formerly published every six months, appears now *every three months*. It is compiled with special reference to being taken *with the Reporter*, and none of the articles which appear in our weekly are reproduced in our quarterly publication. It is made up exclusively from other sources.

Each number of the *Quarterly Compendium* contains 150 pages of reading matter, carefully selected from American, British, and European medical journals, with a special view to the wants of the American physician. It is on excellent paper, and neatly bound in pamphlet form, with full table of contents and index.

The price of the COMPENDIUM is 75 cents a number, or \$2.50 a year; and it will be found well worth it. But when taken with the REPORTER, we offer the two journals at the very low price of SIX DOLLARS, when paid for *strictly in advance* and directly to this office.

THE DIET CURE.

A most fruitful field for investigation, and one that has been comparatively little explored, is that which will unfold to us the intimate influence of our different articles of diet upon the human body in health and disease. When we realize that the food taken into the stomach is destined to be carried to and become most intimate integral portions of every tissue and organ in the body, we must perforce recognize that the nature of our food must have considerable influence upon the nature of the constituents of our bodies, and if, as it seems reasonable to suppose, chronic diseased conditions are characterized by alterations or changes in the composition of our bodies, then might we be allowed to reason, that if we send certain pabulum to these organs and tissues certain effects will result.

Is it too far-fetched to suppose, that the same results which we now achieve by sending drugs to the tissues and organs, may be accomplished by the sending of proper articles of diet?

Food and drugs are each composed of an aggregate of elements that certainly must have definite action on the tissues and functions of our bodies. In this connection it will be interesting to read the following communication from Dr. T. R. Allinson in the *Brit. Med. Jour.*, December 29, 1883:

"I have just concluded an experiment which I think may be of service, or may lead to some observations which may be of use in the prevention and cure of disease. I have discontinued the use of flesh meat for nearly two years; but, on October 19, I left off the use of all animal products, such as milk, butter, cheese, eggs, and honey. My weight was then 9 stones 8 ounces. In a month's time (the time my experiment lasted), my weight was 9 stones, 3 pounds, 12 ounces, or a gain of 3½ pounds. The change was not pleasant at first, as I gave up the use of salt and pepper as well; my food tasted mawkish, and I was soon satisfied; but a week's practice soon made me relish my food, and now salt tastes distasteful. My usual exercise is from ten to fifteen miles a day, and I went on the same as ever, and I seemed none the worse for my change of diet. I even lost my mild bilious feelings, which butter and cheese give rise to. I only broke my experiment once, and that was on November 14, when I had

a piece of cake which had an egg in it, but no butter. I calculated I took then a sixteenth of an egg.

My food was as follows: Breakfast, at 9 a. m., consisted of porridge made from equal parts of oatmeal and wheatmeal. This was followed by a cup of hot water, flavored with fruit syrup and sweetened with sugar. At the same time, I had some bread fried in refined cotton-seed oil, or vegetable haggis fried in the same, the haggis being composed of oatmeal, wheatmeal, tapioca, mixed herbs, and Spanish onion, boiled in a cloth like a pudding. Dinner was taken at 2 or 3 p. m., and consisted of a thick vegetable soup eaten with wholemeal bread, or potato and onion pie, savory pie, vegetarian pie, vegetable stew, stewed rice and tomatoes, etc. This was followed by a bread plum pudding, stewed figs, prunes, or raisins, and bread, or stewed rice and these fruits, etc. Tea meal, at 5.30 p. m., consisted of some fruit syrup and water, or a sup of cocoa. I had with it some bread and jam, stewed fruit, or green stuff, as celery, tomatoes, watermelons, etc. Frequently I had only two meals a day, and a cup of cocoa and a biscuit at 8 p. m. The cost of my diet was a little over twelve cents a day, and I could easily live for less. The quantity was not more than my usual amount. Now I have again returned to milk, butter, eggs, and cheese, when out visiting, but rarely are they seen on my own table.

I think the diet-cure will be found the philosopher's stone of medicine; by diet we can in a great measure prevent seven-tenths almost of our present diseases; or, if disease has set in, then simple food will allow the patient to recover most quickly. Most of our modern diseases can be traced to dietetic errors; excessive flesh-food, and want of active outdoor exercise and fresh air, must be blamed for our diseases. All stomach-complaints, as indigestion, dyspepsia, gastric catarrh, biliousness, congestion of liver, jaundice, gastro-enteritis, hemorrhoids, etc., are due to excess or wrong kinds of food; whilst biliary calculi, urinary calculi, rheumatism, gout, atheroma, Bright's disease, and apoplexy, all point to excess of nitrogenous material, which the system cannot get rid of, and so it remains and produces disease. The kidney being blocked up, more work is thrown on the heart, which then hypertrophies or becomes enlarged, the lungs share in the back-working, and thus the whole system becomes affected. Most of these diseases can be cured, or at least relieved, by a non-flesh diet. Epilepsy is often cured, and always relieved, by such a diet; and even cancer's wasting hand may be partially stopped. Most chronic cases can be relieved by

our diet, and I have known some severe cases of general eczema cured by it alone.

The subject is well worthy of the study of our scientists; and, if possible, I intend showing by experiment how urinary calculi may be dissolved by diet, and so the operation of lithotripsy and lithotomy be avoided in many cases. The great secret of medicine must be, first, prevention; and, second, where disease already exists, its cure. If any one would like to try this diet, I shall be glad to forward them a cookery-book containing over ninety recipes, on receipt of two stamps for postage, etc. It contains many dishes suitable for invalids, convalescents, those in delicate health, and others."

The thoughts suggested in this communication are well worthy of elaboration, and we doubt not that a careful, extended, and concerted inquiry in this direction would be productive of most beneficent results.

THE CASE OF DR. BERNARDY.

Dr. E. P. Bernardy, of the Blockley Hospital, who had charge of the recent epidemic in the Children's Asylum, has handed his resignation to Poor Guardian Ruhl, with the request that it be presented to the Board at its next meeting. The letter reads as follows:

NO. 221 SOUTH SEVENTEENTH STREET,
PHILADELPHIA, February 25, 1884.

TO THE PRESIDENT AND MEMBERS OF THE GUARDIANS OF
THE POOR:

GENTLEMEN: Feeling that my course in not calling a consultation early in the epidemic (which I learn has not been usual) has been unsatisfactory to some of the members, I hereby tender my resignation as member of the Obstetrical Staff of the Philadelphia Hospital—at the same time feeling that I have performed faithfully and conscientiously my whole duty.

Respectfully,

E. P. BERNARDY.

When a man is persecuted, he should be defended; this is a law that is recognized by every right-minded man. We speak from experience, when we say that Dr. Bernardy is right when he says that it has not hitherto been customary to call for consultation in time of epidemics in Blockley. We know of an epidemic of puerperal fever in that institution, wherein thirty out of seventy-five parturient women died; no consultation was held, and no fuss was made about it. We do not argue that such is right and proper: we merely state that such has been the case.

Again, it is well known among all those who know anything about Blockley, that great mortality among the foundlings, when disease gets in among them, is always looked for; the inmates of the Children's Asylum are, for the most part, the offspring of illicit love, crime, drunkenness, and disease; they have been usually abandoned by their parents and subjected to exposure before being brought to the institution, by which the little vitality they have received at birth has been seriously deteriorated; hence they lack the stamina to successfully resist the inroads of disease. We do not wish to be understood as defending Dr. Bernardy's action in not calling for a consultation; for if such a regulation had been passed by the Board of Guardians, and he failed to comply with it, then he was derelict in his duty, and deserved punishment; but if such a regulation had not been made, and we have not heard that it had been, then we say that Dr. Bernardy was unjustly treated, because he was acting in accordance with the *customs* of the institution. Dr. Bernardy may be unpopular (we know nothing about this matter), but the request for his resignation was surely not justified by his action. We have had no conversation with any one about this case, but we feel that a forced resignation from an official position is so calculated to injure a man's reputation, that a vindication should be offered when the premises clearly warrant it. We venture to say that personal considerations had much more to do with Dr. Bernardy's removal than any infringement of rules or neglect of duty.

THE PROPOSED NATIONAL PHARMACOPŒIA.

Some surprise has been manifested in certain quarters that a bill was introduced into the House of Representatives to prepare and publish a National Pharmacopœia. The chief of the Marine Hospital Service, of the Navy, and of the Army are each to detail two medical officers, and the officers are to invite the American Medical Association and the American Pharmaceutical Association to form committees of not more than three members, and thus constituted, this board shall

proceed to the work of forming a new pharmacopœia, which will be published by the Government.

An article in a contemporary tries to make it appear that this project arises from a local rivalry; also that a revision is not needed; and, finally, that the attempt will fail.

Perhaps it will fail. Many laudable efforts do. But we take this occasion to remind the profession and the pharmacists of the United States that the publication of the last edition of the Pharmacopœia was the result of an arrangement which had all the appearance of a discreditable "deal" between the Committee of Publication and a publishing house. We pointed out the facts at the time, gave the names of the committee, and called on them for an explanation. (See *REPORTER*, vol. xlviii, page 105.)

Did they offer any explanation? No. They trusted to silence rather than to trust to an open statement.

Other journals, both of pharmacy and of medicine, repeated these accusations, supporting them with documents. Still no reply from the committee.

The *method of publication*, therefore, stands convicted as an unsound one before the country. The result has been that a publishing house has reaped a rich harvest at the expense of physicians and pharmacists, at the expense of the copyright holders, and at the expense of the good repute of the Committee of Publication.

Was the revision well done? It has been severely criticised, certainly in some respects justly. There can be no doubt but that it would be a great advantage to have it repeated. The complimentary words of a few reviewers cannot stand against the opinion of those who have studied the volume carefully. It is altogether to the interest of both parties interested—pharmacists and physicians—that the Pharmacopœia be a government publication.

THE VIVISECTION QUESTION.

The interest in restraining vivisection continues active in this city. It is, however, not illiberal,

as it has been represented in some quarters. One of our city contemporaries, for instance, writes editorially: "Years ago we offered to accept such a bill as has since been passed in Great Britain. Happily, hysterical counsels prevailed, and the ladies concerned promptly refused any aid which did not concede total abolition."

This is an error. A copy of the bill advocated by the ladies (*i. e.*, the Women's Branch of the Pennsylvania S. P. C. A., Mrs. C. E. White, President) is before us, and it permits any experiment or demonstration whatever under anæsthesia, and any experiment or demonstration without anæsthesia, except such as are "for the purpose of illustrating or demonstrating any fact, process or theory already known to science or medicine." In other words, it did not throw any obstacle in the way of original research. Furthermore, we have the best authority for saying that the ladies never refused any proffered aid in urging this bill.

It is our own opinion that this whole matter of vivisection should be left to the conscience of the profession. We should not object to such a bill as was proposed, except that it assumes to dictate where dictation is out of place—in the conscientious pursuit of scientific truth. No instance has come to our knowledge in this commonwealth where a physician has been charged with needless cruelty to animals used for this purpose. We consider, therefore, that the ladies and their male friends who agitate in this matter are acting unnecessarily and unwisely. There are a thousand cases of human suffering, yes, ten thousand, in this commonwealth, which call for relief, to one case of a cat or dog; and to the simplicity of our mind it would seem more in keeping with true benevolence to look after the former. For all that, we would not have these excellent ladies remain under the burden of any erroneous imputations.

NOTES AND COMMENTS.

An Improved Method of Treating Skin Affections.

Though not new to dermatologists, yet the general profession are not familiar with the method of applying treatment to skin diseases, about

which Dr. P. Albert Morrow writes in the *Medical Record*, March 1, 1884:

The method consists essentially in the application of medicinal substances to the skin in the form of fixed, adhesive preparations. Its object is to confine the application of the drug to the diseased surface alone, and to secure its continued action by maintaining it in prolonged contact with the tissues by means of a practically immovable dressing.

For the attainment of this object a number of procedures have been employed:

1. Applying the drug in the form of a powder or paste, and retaining it in position by means of a protective coating formed by a layer of collodion or a piece of gutta-percha tissue.

2. By an admixture of the drug with a gelatine mass, which is painted over the surface, forming a thin adherent layer, with the addition of glycerine to render it soft and pliable.

3. By the application of a thin layer of collodion or gutta-percha solution, holding the drug in liquid suspension.

4. By incorporating the drug with adhesive plaster muslins, the basis of which is gutta-percha, which are cut into convenient shape so as to admit of accurate adjustment to the affected surface.

It may, perhaps, be considered premature to pronounce positively upon the merits of these preparations, or to decide closely their range of therapeutic application; yet a careful study of the results of their use in the hands of others, supplemented by his own experience, justifies Dr. Morrow in formulating the following conclusions:

That the introduction of fixed, adhesive applications in the treatment of certain forms of skin affections, marks a veritable advance in cutaneous therapeutics.

That they are admirably adapted for the employment of certain powerful stimulating drugs recently introduced into dermatological practice, as well as other standard drugs.

That they constitute the most effective mode of applying drugs in certain pathological conditions characterized by hyperæmia of the derma with inflammatory overgrowth of the epithelial elements, as in psoriasis and dry, scaly eczema.

In conditions characterized by hyperplasia of the cuticle, as in callosities, corns, and overgrowths of thickened, hardened epidermis, etc.

In conditions of capillary congestions of a passive character, as in acne rosacea, chronic erythema, etc.

In certain neurotic conditions, not only in essen-

tially pruriginous diseases, as prurigo, but in the pruritus symptomatic of other affections.

In circumscribed lesions generally, as *tinea circinata*, *tinea capitis*, *eczema marginatum*, *chromophytosis*, syphilitic scleroses, lupus, and, possibly, epithelioma.

Sacrache and Back-Ache.

In the course of some interesting lectures by Dr. J. Mathews Duncan, in the *London Medical Times*, we note the following, which is possessed of practical interest:

There is no more common, and therefore no more important, symptom of uterine disease, and especially of disease of the neck of the womb, than sacrache. The pain is dull, or an ache rather than pain: it is situated at or near the base of the sacrum; and, referring to it, the patient puts her hand to the part. I say with emphasis "at or near," and it is desirable to make this more definite. A pain below the middle of the sacrum is not at or near, and a pain above the middle of the lumbar spine is not "at or near." Such pains and aches do not point to the womb as the characteristic sacrache does; but the characteristic sacrache only points in that direction: it is not in itself nearly sufficient, not even strong, evidence of disease of the womb. Occurring in a virgin it would not, alone, unless very severe and inveterate, lead you to make an actual examination of the womb.

Other back-aches, that is pains in other regions of the back, not the sacrache, may accompany uterine disease, but do not point to the womb, are not symptoms rationally held as indicating womb disease. Unfortunately women are, at present, so under the influence of bad medical instruction, that they regard all pains in the back, from the occiput to the coccyx, as nearly sure indication of uterine mischief, and demanding uterine treatment.

The sacrache of womb disease may be constant, but generally it comes and goes. Frequently it is dispelled by lying, is felt on going to bed, and has disappeared before morning, and long standing makes it reach its highest pitch. When it is otherwise, that is when the ache is worse in the morning before getting out of bed, or is relieved by walking, then it is certainly not uterine.

I have said that you must not regard all sacraches or other back aches as uterine. They are common in men and in women. A weakly woman, who attends to all her pains, can do no standing or walking without back-ache, and often it is a sacrache; especially, if she has a long back, will she suffer in this way.

The pains liable to be confused with real sacrache are all in the lower back, about the lumbar spine: it is only such that might mislead any rational physician. Regarding them you will get some light from noticing the causes of the same pains in men. Now I find that weakly men are liable to these aches, sacral or lumbar, on walking or standing; and in many they are produced by excessive venereal indulgence.

Alcoholic Leg-Pains.

In the *Brit. Med. Jour.*, Dr. T. Clifford Allbutt writes:

"In the *Journal* of January 26, I observe a letter from 'Quærens,' who asks concerning 'tibial pains' in a hard drinker. These pains are so characteristic and so often met with, that I feel surprise that they have received but little attention. Indeed, I cannot call to mind any description of them in medical literature, nor do I find that my medical friends know much of them. These pains are commoner in women than in men; they are often tibial in distribution, but occur also often about the ankles and feet. They are usually associated with marked cutaneous hyperæsthesia. I have diagnosed in women many a case of secret drinking by these pains alone. Indeed, if a woman were found to complain bitterly of pains in the legs below the knees, pains somewhat nocturnal in occurrence, and as severe as those of syphilitic periostitis; if she resented any free handling of the limbs; if, again, she lay with legs adducted, extended, and with the feet pointed, much as in lateral sclerosis, but without permanent rigidity; if for all this outcry there were no visible cause whatever, the tibiæ smooth, and no more sign of spinal disease than perhaps a slight ankle-clonus, then I should, almost without hesitation, infer that alcohol was the cause. As 'Quærens' finds, the pains cannot readily be eased, and can be cured only by time, with abstinence. In his case, I suspect the cause is still in operation. For my own part, I tell my patient how he is to promote his own cure, and am not sorry to use the pains as an argument for abstinence. I feel little doubt that the cause of them lies in the irritation of the spinal cord or its membranes."

Dr. A. is an authority, but the question suggests itself to us, whether these pains are not really syphilitic in character. We do not mean to say that all hard drinkers are syphilitic, but we do believe that the majority of syphilitics are hard drinkers. A sober man is usually careful about sexual intercourse, while if the question were put to all

syphilitics, we feel that the greater proportion would answer that the intercourse from which they contracted the disease was indulged in when drunk and irresponsible. Having become syphilitized, the spirits are naturally much depressed, and, in many cases, spirits are poured down to keep the spirits up. Again, it is well known that alcohol has a tendency to exaggerate the symptoms of syphilis, no doubt by its depressing influence on the general system. In this last fact may possibly be found an explanation of the fact that the pains were cured by abstinence.

The Pathology of Puerperal Fever.

When Dr. C. C. Lee (New York Pathological Society) says that a woman died of "unmistakable puerperal fever," one is inclined to ask, what is "puerperal fever?" in view of the diversity of opinion on the subject which recent discussions in New York have brought forth. Puerperal fever is a very safe expression, because in all these cases there is undoubtedly fever, and since this fever occurs in a puerperal woman, it must perforce be *puerperal fever*, no matter what the cause may be. The specimens which Dr. Lee presented argue strongly in favor of the view that puerperal fever is due to puerperal *septicæmia*, whether the *septicæmia* be due to the entrance of disease germs from without or to the results of decomposition of placental fragments and blood-clots that have been retained in an imperfectly involuted uterus—which latter view receives the sanction of Professor Parvin to a certain extent, who seems to believe that the placental and blood-clot debris furnish nourishment to the germs from without. The italicized words (our own italics) that follow will make this view clear.

Examination of the abdomen only was allowed. The intestines were distended with gas. The peritoneum was cloudy and covered with a pellicle of fibrin and pus, best seen where the coils of intestine came in contact. There was a small amount of sero-purulent fluid within the peritoneal cavity. The stomach was enormously distended with gas. The uterus was partially involuted. There were no adhesions. The outer surface of the organ was pale. There was no exudation upon it. There was no evidence of cellulitis. The uterus was opened on the anterior, and the interior was found to contain dirty brown granular matter, irregularly heaped up, the greatest thickness being about one-eighth of an inch. The odor was offensive, although not strictly fetid. These pulpy masses seemed to be from broken-down clots. No fibres were found, and they were easily washed away. *Inflammatory*

products, pus and fibrin, in small amount, thinly scattered over the whole of the inner surface, more especially in the lower half. The kidneys exhibited no evidence of pathological change.

Suspended Animation.

A very interesting theological question is raised by the following case reported by Dr. W. Augustus Norry in the *Brit. Med. Jour.*, January 26, 1884:

I was called to attend A. B., a primipara, who was stated to be in the seventh month of pregnancy. I found the os slightly dilated, and labor commenced. About eight hours afterwards, the patient was delivered of a seven months' female child. When born, the child was apparently dead. Artificial respiration was performed, the heart then feebly pulsating; cold and hot baths, with slight blood-letting from the umbilical cord, were also tried. This produced one or two gasps, but the limbs became cold, and the heart's action stopped. After half to three-quarters of an hour had been spent in fruitless endeavors to restore animation, the child was given to the nurse as dead, and placed in a flannel. It lay there for about two hours. When the nurse went to move it to a proper place, she observed it give a gasp, whereupon she put it into a warm bath; and after a while its color and the heart's pulsations returned. It lived about fifteen hours.

The point of interest to a general practitioner from this case is the question, How long should an attempt to restore life be made?—as to a busy man it must of necessity be a very material point whether he has to stay half an hour or two hours after the heart and respiration have both stopped. On the other hand, a life is at stake, and the interest of that young life must be duly considered.

If in similar cases the child is regarded as dead, and no efforts made to resuscitate, what will be the future condition of that child?—for in such a case a living being has died without baptism!

Sea Voyaging.

We are so accustomed to recommend a sea voyage to a patient whom we are not able otherwise to benefit, that it has become a therapeutic routine, and we rarely hesitate to consider the appropriateness of our recommendation. In the *Lancet*, February 23, Dr. Farquhar publishes a paper on Sea Change, the Effects of Voyaging, with cases. He remarks on the paucity of information on this subject, Dr. Faber being the only observer who

had gone to work systematically. Dr. Farquhar's observations on a voyage last winter up the Mediterranean led him to the belief that many unsuitable cases are sent a-voyaging by medical men; and in the event of such a rigorous winter as that of last year, even in Italy and Greece, the disappointment to invalids in search of health must be great. He then gives details of the various cases that came under his care and observation. The most pronounced benefit was obtained by most of the phthisical cases, but some left the steamer before the tonic and stimulating action of the sea air had made itself felt, unnerved by the hardships endured in a storm experienced on leaving the Mersey. Voyagers suffering from the effects of overwork and mental strain did well; but "specific" cases showed the most marvellous results, complete recovery being the rule. Dyspeptics did not do well, nor subjects of skin disease of a nervous origin. To sum up, his experience in this voyage led him to believe that no diseased condition where the nervous, irritable element was present had much chance of benefit: the sea-air stimulus was in the end too powerful through its constancy. Such cases should land after the first beneficial stimulation, which generally occurred within the first three or four weeks of the voyage.

Confinement vs. Consumption.

We all know that fresh air and consumption are very antagonistic, and as affording additional evidence of this, the observations of Dr. Baer, chief medical officer at the Plötzensee Prison, near Berlin, have demonstrated the fact that the mortality in the State prisons for the three years 1878 to 1880, represented an annual death-rate of 30.6 per thousand. In describing the general results of his experience, in the *Zeitschrift für Klinische Medicin*, he alludes to the fact that previous to the improvement in prison arrangements, which was brought about early in the present century, malignant typhus, gaol fever, and small-pox, decimated the inmates of such establishments. At a later period, when, notwithstanding the advances made in the direction of reform, prisoners were kept in unhealthy cells, and were fed insufficiently as well as injudiciously, scorbutic affections and diarrhoea became frequent. Now that in most instances the arrangement of prisons is in accordance with sanitary requirements, it would seem that consumption has taken a leading position amongst the recorded causes of mortality. Various statistics as to the last fifty years are quoted by Dr. Baer in confirmation of these assertions.

As to the institution under the care of Dr. Baer, it would appear that between 1873 and 1882 only $6\frac{1}{2}$ per cent. of the deaths were attributed to consumption, but out of 112 cases in which prisoners were discharged upon medical grounds, 45 were suffering from the disease in various stages. As to the disease being brought on by confinement in prison, Dr. Baer considers this is proved by the facts that the greatest mortality is traced to the second and third years of captivity, and that persons in solitary confinement have been found to be frequently attacked by the disease in question.

Near-sighted Children.

At a recent discussion in England on the growing frequency of myopia in schools, one of the speakers mentioned the importance of any improvements that would keep the scholar's eye at a good distance from his task. The ordinary slates in common use have long been felt to be unsatisfactory, on account of the little contrast between their surfaces and the markings of the pencil, and which was rendered even less when the slate had become greasy. Allusion was made to the greater contrast of pen and ink marks on white paper, and to the experiments in schools at Zurich, under Professor Horner, where ink and paper were adopted in preference to slates. Cohn, of Breslau, had, however, devised white composition slates. An ordinary lead, or a specially used black pencil, was employed. Other marks were easily erased. Reference was briefly made also to the printing of school books, and to the very valuable and interesting articles in the *Annales d'Oculistique* some time since on the "Physiology of Reading," by Javal. This observer has made the important discovery that on reading the eye runs along the upper part of a line, and see it more clearly than the lower half. Examples of printing illustrating this were shown, and the explanation by Javal was mentioned, as well as the hints this observer drew from this fact for the formation of type.

Hyperosmic Acid for Neuralgia.

From the *Med. Record* we learn that a one per cent. solution of this drug has been used subcutaneously. It has been employed in Billroth's clinic in a few cases. One of the patients had been a martyr to sciatica for years, and had tried innumerable remedies, including the application of electricity no fewer than 200 times, while for a whole year he had adopted vegetarianism. Billroth injected the above remedy between the tuber ischii and trochanter, and within a day or two

the pain was greatly relieved, and eventually quite disappeared. It would be rash to conclude too much from these results, in the face of the intractability of neuralgia to medication; but if it really prove to be as efficacious as considered, hyperosmic acid will be a therapeutic agent of no mean value.

A Caution about Jequirity.

After reporting a case of sloughing of the cornea after the use of jequirity, in the *Weekly Medical Review*, February 23, 1884, Dr. S. Pollak formulates as follows:

1. Jequirity is by far the best remedy which has been hitherto used for trachoma and pannus.

2. It does all, and more speedily, that has ever been claimed for purulent inoculation, minus the repulsiveness of the last remedy.

3. The infusion of jequirity must be used only when perfectly fresh. After four or five days it swarms with bacteria, when the danger of their entering the tissue and causing a septic state is very great.

4. Sterilizing the infusion requires much care and labor, and may not always be practicable. It will doubtless retard the decomposition, but it will not prevent it entirely.

5. The full therapeutic utility of jequirity will only be attained when chemistry shall have succeeded in preparing an alkaloid of it, which will keep, and the strength of it is properly known.

Calcification of the Pleura Costalis.

As evidencing how wonderful may be the morbid processes going on within the body, we note the following from the *Brit. Med. Jour.*, January 26, 1884: At the *post mortem* examination of a man who had died of cancer of the stomach, at the Hôpital St. Antoine, M. Gilbert found a thick plate of bone-like material covering the internal surface of the ribs on the right side, from the sternum to the vertebral column. This plate measured 12 centimetres in height, and 20 in breadth. Its external surface was smooth, and separated from the ribs by connective tissue, while the internal was rough, and adherent in some places to the lung. Chemically, the plate had very nearly the same composition as bone, but the microscopical examination showed that it was only fibrous tissue loaded with lime-salts.

Bert on Chloroformization.

A foreign exchange notes that M. Bert promises to arrive at a method of administering chloroform

mixed with oil, which will render the use of an apparatus unnecessary, but will yet be superior to that which consists in the application of a compress, saturated or moistened with the anæsthetic administered. He observes that it is barely possible that country practitioners who are only occasionally called upon to use chloroform, can purchase an instrument costing \$40, and keep it in order. Therefore, at a future meeting of the Biological Society, he will describe a method he calls *procédé de campagne* (country method), in contradistinction to the *procédé de ville* (town apparatus), when an apparatus is used.

Woman's Place in Nature.

If the result of the highest vitality is the most perfect product, we can scarcely refuse to the female the advantage over the male. It appears to be a well-established fact that an important source of sexual determination is nutritive as far as ovum development is concerned: that is, when the force becomes partially exhausted, the result is the production of males; when the ovum is in the maximum of sexual potency, then the production is invariably females. Does not this seem to indicate that there is something finer, subtler, more perfect, in the organization of woman?

Modern Operations for Cataract.

Mr. Brudenell Carter thus tersely summarizes his three lectures on this subject: They showed that the performance of iridectomy as a preliminary operation, and the subsequent employment of a comparatively small section through the tunics of the eye, have combined to render the extraction of cataract a more simple, and hence a more frequently successful operation than it has been at any previous period, and that these improved methods now enable surgeons to deal with the disease at a comparatively early period of its history.

For Flesh Worms.

Hager's Pharm. Cent., December 27, 1883, has the following:

Sixty-five grammes pure kaolin, fifty grammes glycerine, and thirty-three grammes dilute acetic acid, well mixed and formed into a paste and applied upon parts afflicted before retiring to bed, and left until next morning. The following evening rub parts at first gently with levigated pumice-stone upon flannel, and then increase friction. This treatment is continued alternately, one evening with paste and the next with pumice, until the flesh-worms have disappeared.

CORRESPONDENCE.

Answer to Gynæcological Queries.

EDS. MED. AND SURG. REPORTER:—

"Medica's" query No. 1 in your valuable journal, February 23, gives the symptoms that if varied in some cases would describe the condition of many patients that fall into the hands of physicians; and, like M.'s patient, they generally pass through the hands of all the doctors within their reach, with but little or no improvement. I have reference to the rural practitioner. Of course there are specialists in the larger cities whose experience and facilities enable them to relieve promptly and permanently a large majority of patients similar to the one under consideration; but unfortunately it is not possible for the greater portion of suffering women to avail themselves of the skill of the specialist, hence there is the great mass that must depend on the skill of the country practitioner for their health and happiness, and it is for the benefit of this class I call the attention of the reader.

That the treatment of this class of patients as practiced by the rural doctors is unsatisfactory, I do not think there can be any doubt; and, like M., there are, perhaps, many of your readers that would like to have a substitute for the disagreeable and inefficient astringent injections, which, in my hands, have proved an utter failure in a large majority of cases—and I know of other physicians whose experience has been similar to my own.
